exception handling, which is why we introduced the basics of exception handling in Chapter 5. However, the need to deal with run-time errors tends to be more important and harder to manage in problems that require large programming teams. In Chapter 18 we review some additional useful exception-handling facilities. We also look in more detail at how exceptions are handled, and show how we can define and use our own exception classes. This section will also cover improvements from the new standard regarding specifying that a particular function will not throw.

Large-scale applications often use code from multiple independent vendors. Combining independently developed libraries would be difficult (if not impossible) if vendors had to put the names they define into a single namespace. Independently developed libraries would almost inevitably use names in common with one another; a name defined in one library would conflict with the use of that name in another library. To avoid name collisions, we can define names inside a namespace.

Whenever we use a name from the standard library, we are using a name defined in the namespace named std. Chapter 18 shows how we can define our own namespaces.

Chapter 18 closes by looking at an important but infrequently used language feature: multiple inheritance. Multiple inheritance is most useful for fairly complicated inheritance hierarchies.

Chapter 19 covers several specialized tools and techniques that are applicable to particular kinds of problems. Among the features covered in this chapter are how to redefine how memory allocation works; C++ support for run-time type identification (RTTI), which let us determine the actual type of an expression at run time; and how we can define and use pointers to class members. Pointers to class members differ from pointers to ordinary data or functions. Ordinary pointers only vary based on the type of the object or function. Pointers to members must also reflect the class to which the member belongs. We'll also look at three additional aggregate types: unions, nested classes, and local classes. The chapter closes by looking briefly at a collection of features that are inherently nonportable: the volatile qualifier, bit-fields, and linkage directives.

Section 17.4 Random Numbers

Section 17.5 The IO Library Revisited

Chapter Summary Defined Terms

The latest standard greatly increased the size and scope of the library. Indeed, the portion of the standard devoted to the library more than doubled between the first release in 1998 and the 2011 standard. As a result, covering every C++ library class is well beyond the scope of this Primer. However, there are four library facilities that, although more specialized than other library facilities we've covered, are general enough to warrant discussion in an introductory book: tuples, bitsets, randomnumber generation, and regular expressions. In addition, we will also cover some additional, special-purpose parts of the IO library.

The library constitutes nearly two-thirds of the text of the new standard. Although we cannot cover every library facility in depth, there remain a few library facilities that are likely to be of use in many applications: tuples, bitsets, regular expressions, and random numbers. We'll also look at some additional IO library capabilities: format control, unformatted IO, and random access.

17.1. The tuple Type

A tuple is a template that is similar to a pair (§ 11.2.3, p. 426). Each pair type has different types for its members, but every pair always has exactly two members. A tuple also has members whose types vary from one tuple type to another, but a tuple can have any number of members. Each distinct tuple type has a fixed number of members, but the number of members in one tuple type can differ from the number of members in another.

A tuple is most useful when we want to combine some data into a single object but do not want to bother to define a data structure to represent those data. Table 17.1 lists the operations that tuples support. The tuple type, along with its companion types and functions, are defined in the tuple header.

Table 17.1. Operations on tuples

```
tuple<T1, T2, ..., Tn> t;
             t is a tuple with as many members as there are types T1 ... Tn. The members
             are value initialized (§ 3.3.1, p. 98).
tuple<T1, T2, ..., Tn> t(v1, v2, ..., vn);
             t is a tuple with types T1...Tn in which each member is initialized from the
             corresponding initializer, v_i. This constructor is explicit (§ 7.5.4, p. 296).
make tuple(v1, v2, ..., vn)
             Returns a tuple initialized from the given initializers. The type of the tuple
             is inferred from the types of the initializers.
t1 == t2
            Two tuples are equal if they have the same number of members and if each
             pair of members are equal. Uses each member's underlying == operator. Once
t1 != t2
             a member is found to be unequal, subsequent members are not tested.
t1 relop t2 Relational operations on tuples using dictionary ordering (§ 9.2.7, p. 340). The
             tuples must have the same number of members. Members of tl are
             compared with the corresponding members from t2 using the < operator
get<i>>(t) Returns a reference to the ith data member of t; if t is an Ivalue, the result is
             an Ivalue reference; otherwise, it is an rvalue reference. All members of a
             tuple are public.
tuple size<tupleType>::value
             A class template that can be instantiated by a tuple type and has a public
             constexpr static data member named value of type size t that is
             number of members in the specified tuple type.
tuple element<i, tupleTupe>::type
             A class template that can be instantiated by an integral constant and a tuple
             type and has a public member named type that is the type of the specified
             members in the specified tuple type.
```

A tuple can be thought of as a "quick and dirty" data structure.

17.1.1. Defining and Initializing tuples

When we define a tuple, we name the type(s) of each of its members:

Click here to view code image

```
tuple<size_t, size_t, size_t> threeD; // all three members set to 0
tuple<string, vector<double>, int, list<int>>
    someVal("constants", {3.14, 2.718}, 42, {0,1,2,3,4,5});
```

When we create a tuple object, we can use the default tuple constructor, which value initializes (§ 3.3.1, p. 98) each member, or we can supply an initializer for each member as we do in the initialization of someVal. This tuple constructor is explicit (§ 7.5.4, p. 296), so we must use the direct initialization syntax:

Click here to view code image

```
tuple<size_t, size_t, size_t> threeD = {1,2,3}; // error
tuple<size_t, size_t, size_t> threeD{1,2,3}; // ok
```

Alternatively, similar to the make_pair function (§ 11.2.3, p. 428), the library defines a make_tuple function that generates a tuple object:

Click here to view code image

```
// tuple that represents a bookstore transaction: ISBN, count, price per book
auto item = make_tuple("0-999-78345-X", 3, 20.00);
```

Like make_pair, the make_tuple function uses the types of the supplied initializers to infer the type of the tuple. In this case, item is a tuple whose type is tuple<const char*, int, double>.

Accessing the Members of a tuple

A pair always has two members, which makes it possible for the library to give these members names (i.e., first and second). No such naming convention is possible for tuple because there is no limit on the number of members a tuple type can have. As a result, the members are unnamed. Instead, we access the members of a tuple through a library function template named **get**. To use get we must specify an explicit template argument (§ 16.2.2, p. 682), which is the position of the member we want to access. We pass a tuple object to get, which returns a reference to the specified member:

Click here to view code image

```
auto book = get<0>(item);  // returns the first member of item
auto cnt = get<1>(item);  // returns the second member of item
auto price = get<2>(item)/cnt; // returns the last member of item
get<2>(item) *= 0.8;  // apply 20% discount
```

The value inside the brackets must be an integral constant expression (\S 2.4.4, p. 65). As usual, we count from 0, meaning that get<0> is the first member.

If we have a tuple whose precise type details we don't know, we can use two auxilliary class templates to find the number and types of the tuple's members:

Click here to view code image

```
typedef decltype(item) trans; // trans is the type of item
// returns the number of members in object's of type trans
size_t sz = tuple_size<trans>::value; // returns 3
// cnt has the same type as the second member in item
tuple_element<1, trans>::type cnt = get<1>(item); // cnt is an
int
```

To use tuple size or tuple element, we need to know the type of a tuple object. As usual, the easiest way to determine an object's type is to use decltype (§ 2.5.3, p. 70). Here, we use decltype to define a type alias for the type of item, which we use to instantiate both templates.

tuple_size has a public static data member named value that is the number or members in the specified tuple. The tuple_element template takes an index as well as a tuple type, tuple element has a public type member named type that is the type of the specified member of the specified tuple type. Like get, tuple element uses indices starting at 0.

Relational and Equality Operators

The tuple relational and equality operators behave similarly to the corresponding operations on containers (§ 9.2.7, p. 340). These operators execute pairwise on the members of the left-hand and right-hand tuples. We can compare two tuples only if they have the same number of members. Moreover, to use the equality or inequality operators, it must be legal to compare each pair of members using the == operator; to use the relational operators, it must be legal to use <. For example:

Click here to view code image

```
tuple<string, string> duo("1", "2");
tuple<size_t, size_t> twoD(1, 2);
bool b = (duo == twoD); // error: can't compare a size_t and a string
tuple<size_t, size_t, size_t> threeD(1, 2, 3);
b = (twoD < threeD); // error: differing number of members
tuple<size_t, size_t> origin(0, 0);
b = (origin < twoD); // ok: b is true
```

Because tuple defines the < and == operators, we can pass sequences of tuples to the algorithms and can use a tuple as key type in an ordered container.

Exercises Section 17.1.1

Exercise 17.1: Define a tuple that holds three int values and initialize the members to 10, 20, and 30.

Exercise 17.2: Define a tuple that holds a string, a vector<string>, and a pair<string, int>.

Exercise 17.3: Rewrite the TextQuery programs from § 12.3 (p. 484) to use a tuple instead of the QueryResult class. Explain which design you

17.1.2. Using a tuple to Return Multiple Values

A common use of tuple is to return multiple values from a function. For example, our bookstore might be one of several stores in a chain. Each store would have a transaction file that holds data on each book that the store recently sold. We might want to look at the sales for a given book in all the stores.

We'll assume that we have a file of transactions for each store. Each of these perstore transaction files will contain all the transactions for each book grouped together. We'll further assume that some other function reads these transaction files, builds a vector<Sales_data> for each store, and puts those vectors in a vector of vectors:

Click here to view code image

```
// each element in files holds the transactions for a particular store
vector<vector<Sales_data>> files;
```

We'll write a function that will search files looking for the stores that sold a given book. For each store that has a matching transaction, we'll create a tuple to hold the index of that store and two iterators. The index will be the position of the matching store in files. The iterators will mark the first and one past the last record for the given book in that store's vector<Sales_data>.

A Function That Returns a tuple

We'll start by writing the function to find a given book. This function's arguments are the vector of vectors just described, and a string that represents the book's ISBN. Our function will return a vector of tuples that will have an entry for each store with at least one sale for the given book:

Click here to view code image

The for loop iterates through the elements in files. Those elements are themselves vectors. Inside the for we call a library algorithm named equal_range, which operates like the associative container member of the same name (§ 11.3.5, p. 439). The first two arguments to equal_range are iterators denoting an input sequence (§ 10.1, p. 376). The third argument is a value. By default, equal_range uses the < operator to compare elements. Because Sales_data does not have a < operator, we pass a pointer to the compareIsbn function (§ 11.2.2, p. 425).

The equal_range algorithm returns a pair of iterators that denote a range of elements. If book is not found, then the iterators will be equal, indicating that the range is empty. Otherwise, the first member of the returned pair will denote the first matching transaction and second will be one past the last.

Using a tuple Returned by a Function

Once we have built our vector of stores with matching transactions, we need to process these transactions. In this program, we'll report the total sales results for each store that has a matching sale:

Click here to view code image

The while loop repeatedly reads the istream named in to get the next book to process. We call findBook to see if s is present, and assign the results to trans. We use auto to simplify writing the type of trans, which is a vector of tuples.

If trans is empty, there were no sales for s. In this case, we print a message and return to the while to get the next book to look for.

The for loop binds store to each element in trans. Because we don't intend to change the elements in trans, we declare store as a reference to const. We use get to print the relevant data: get<0> is the index of the corresponding store, get<1> is the iterator denoting the first transaction, and get<2> is the iterator one past the last.

Because Sales_data defines the addition operator (§ 14.3, p. 560), we can use the library accumulate algorithm (§ 10.2.1, p. 379) to sum the transactions. We pass a Sales_data object initialized by the Sales_data constructor that takes a string (§ 7.1.4, p. 264) as the starting point for the summation. That constructor initializes the bookNo member from the given string and the units_sold and revenue members to zero.

Exercises Section 17.1.2

Exercise 17.4: Write and test your own version of the findBook function.

Exercise 17.5: Rewrite findBook to return a pair that holds an index and a pair of iterators.

Exercise 17.6: Rewrite findBook so that it does not use tuple or pair.

Exercise 17.7: Explain which version of findBook you prefer and why.

Exercise 17.8: What would happen if we passed Sales_data() as the third parameter to accumulate in the last code example in this section?

17.2. The bitset Type

In § 4.8 (p. 152) we covered the built-in operators that treat an integral operand as a collection of bits. The standard library defines the **bitset** class to make it easier to use bit operations and possible to deal with collections of bits that are larger than the longest integral type. The bitset class is defined in the bitset header.

17.2.1. Defining and Initializing bitsets

Table 17.2 (overleaf) lists the constructors for bitset. The bitset class is a class template that, like the array class, has a fixed size (§ 9.2.4, p. 336). When we define a bitset, we say how many bits the bitset will contain:

Click here to view code image

bitset<32> bitvec(1U); // 32 bits; low-order bit is 1, remaining bits are 0

Table 17.2. Ways to Initialize a bitset

bitset <n></n>	b;	b has n bits; each bit is 0. This constructor is a constexpr (§ 7.5.6, p. 299).
bitset <n></n>	b(u);	b is a copy of the n low-order bits of unsigned long long value u. If n is greater than the size of an unsigned long long, the high-order bits beyond those in the unsigned long long are set to zero. This constructor is a constexpr (§ 7.5.6, p. 299).
bitset <n></n>	b(s,	pos, m, zero, one); b is a copy of the m characters from the string s starting at position pos. s may contain only the characters zero and one; if s contains any other character, throws invalid_argument. The characters are stored in b as zeor and one, respectively. pos defaults to 0, m defaults to string::npos, zero defaults to '0', and one defaults to '1'.
bitset <n></n>	b(cp,	pos, m, zero, one); Same as the previous constructor, but copies from the character array to which cp points. If m is not supplied, then cp must point to a C-style string. If m is supplied, there must be at least m characters that are zero

The size must be a constant expression (§ 2.4.4, p. 65). This statement defines bitvec as a bitset that holds 32 bits. Just as with the elements of a vector, the bits in a bitset are not named. Instead, we refer to them positionally. The bits are numbered starting at 0. Thus, bitvec has bits numbered 0 through 31. The bits starting at 0 are referred to as the low-order bits, and those ending at 31 are referred to as high-order bits.

Initializing a bitset from an unsigned Value

When we use an integral value as an initializer for a bitset, that value is converted to unsigned long long and is treated as a bit pattern. The bits in the bitset are a copy of that pattern. If the size of the bitset is greater than the number of bits in an unsigned long long, then the remaining high-order bits are set to zero. If the size of the bitset is less than that number of bits, then only the low-order bits from the given value are used; the high-order bits beyond the size of the bitset object are discarded:

Click here to view code image

```
// bitvec1 is smaller than the initializer; high-order bits from the initializer are
discarded
bitset<13> bitvec1 (0xbeef); // bits are 1111011101111
// bitvec2 is larger than the initializer; high-order bits in bitvec2 are set to zero
bitset<20> bitvec2(0xbeef); // bits are 00001011111011101111
// on machines with 64-bit long long OULL is 64 bits of 0, so ~OULL is 64 ones
bitset<128> bitvec3(~0ULL); // bits 0 ... 63 are one; 63 ... 127 are zero
```

Initializing a bitset from a string

We can initialize a bitset from either a string or a pointer to an element in a character array. In either case, the characters represent the bit pattern directly. As usual, when we use strings to represent numbers, the characters with the lowest indices in the string correspond to the high-order bits, and vice versa:

Click here to view code image

```
bitset<32> bitvec4("1100"); // bits 2 and 3 are 1, all others are 0
```

If the string contains fewer characters than the size of the bitset, the high-order bits are set to zero.

The indexing conventions of strings and bitsets are inversely related: The character in the string with the highest subscript (the rightmost character) is used to initialize the low-order bit in the bitset (the bit with subscript 0). When you initialize a bitset from a string, it is essential to remember this difference.

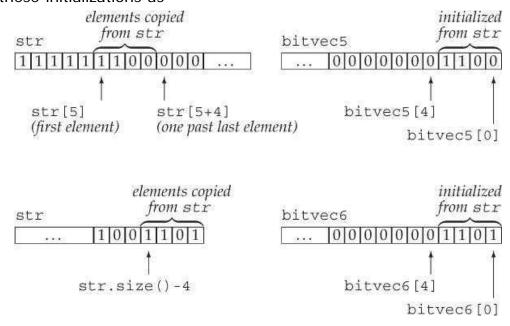

We need not use the entire string as the initial value for the bitset. Instead, we can use a substring as the initializer:

Click here to view code image

```
string str("1111111100000011001101");
bitset<32> bitvec5(str, 5, 4); // four bits starting at str[5], 1100
bitset<32> bitvec6(str, str.size()-4); // use last four characters
```

Here bitvec5 is initialized by the substring in str starting at str[5] and continuing for four positions. As usual, the right-most character of the substring represents the lowest-order bit. Thus, bitvec5 is initialized with bit positions 3 through 0 set to 1100 and the remaining bits set to 0. The initializer for bitvec6 passes a string

and a starting point, so bitvec6 is initialized from the characters in str starting four from the end of str. The remainder of the bits in bitvec6 are initialized to zero. We can view these initializations as

Exercises Section 17.2.1

Exercise 17.9: Explain the bit pattern each of the following bitset objects contains:

- (a) bitset<64> bitvec(32);
- **(b)** bitset<32> bv(1010101);
- (c) string bstr; cin >> bstr; bitset<8>bv(bstr);

17.2.2. Operations on bitsets

The bitset operations (Table 17.3 (overleaf)) define various ways to test or set one or more bits. The bitset class also supports the bitwise operators that we covered in § 4.8 (p. 152). The operators have the same meaning when applied to bitset objects as the built-in operators have when applied to unsigned operands.

Table 17.3. bitset Operations

```
b.any()
                  Is any bit in b on?
b.all()
                   Are all the bits in b on?
b.none()
                   Are no bits in b on?
b.count()
                   Number of bits in b that are on.
                   A constexpr function (§ 2.4.4, p. 65) that returns the number of bits in b.
b.size()
b.test(pos)
                   Returns true if bit at position pos is on, false otherwise.
                  Sets the bit at position pos to the bool value v. v defaults to true. If no
b.set(pos, v)
                   arguments, turns on all the bits in b.
b.set()
                  Turns off the bit at position pos or turns off all the bits in b.
b.reset(pos)
b.reset()
                  Changes the state of the bit at position pos or of every bit in b.
b.flip(pos)
b.flip()
                   Gives access to the bit in b at position pos; if b is const, then b [pos]
b[pos]
                   returns a bool value true if the bit is on, false otherwise.
                   Returns an unsigned long or an unsigned long long with the same
b.to ulong()
                  bits as in b. Throws overflow error if the bit pattern in b won't fit in
b.to ullong()
                   the indicated result type.
b.to string(zero, one)
                   Returns a string representing the bit pattern in b. zero and one
                   default to '0' and '1' and are used to represent the bits 0 and 1 in b.
                   Prints the bits in b as the characters 1 or 0 to the stream os.
os << b
is >> b
                   Reads characters from is into b. Reading stops when the next character
                   is not a 1 or 0 or when b. size () bits have been read.
```

Several operations—<code>count</code>, <code>size</code>, all, any, and <code>none</code>—take no arguments and return information about the state of the entire <code>bitset</code>. Others—<code>set</code>, <code>reset</code>, and <code>flip</code>—change the state of the <code>bitset</code>. The members that change the <code>bitset</code> are overloaded. In each case, the version that takes no arguments applies the given operation to the entire set; the versions that take a position apply the operation to the given bit:

Click here to view code image

```
bitset<32> bitvec(1U); // 32 bits; low-order bit is 1, remaining bits are 0
bool is set = bitvec.any();
                                       // true, one bit is set
bool is_not_set = bitvec.none(); // false, one bit is set
bool all_set = bitvec.all();
                                       // false, only one bit is set
size_t onBits = bitvec.count();
                                      // returns 1
size_t sz = bitvec.size();
                                       // returns 32
bitvec.flip();
                      // reverses the value of all the bits in bitvec
                      // sets all the bits to 0
bitvec.reset();
                       // sets all the bits to 1
bitvec.set();
```

The any operation returns true if one or more bits of the bitset object are turned on—that is, are equal to 1. Conversely, none returns true if all the bits are zero. The

new standard introduced the all operation, which returns true if all the bits are on. The count and size operations return a size_t (§ 3.5.2, p. 116) equal to the number of bits that are set, or the total number of bits in the object, respectively. The size function is a constexpr and so can be used where a constant expression is required (§ 2.4.4, p. 65).

The flip, set, reset, and test members let us read or write the bit at a given position:

Click here to view code image

```
bitvec.flip(0); // reverses the value of the first bit
bitvec.set(bitvec.size() - 1); // turns on the last bit
bitvec.set(0, 0); // turns off the first bit
bitvec.reset(i); // turns off the ith bit
bitvec.test(0); // returns false because the first bit is off
```

The subscript operator is overloaded on const. The const version returns a bool value true if the bit at the given index is on, false otherwise. The nonconst version returns a special type defined by bitset that lets us manipulate the bit value at the given index position:

Click here to view code image

Retrieving the Value of a bitset

The to_ulong and to_ullong operations return a value that holds the same bit pattern as the bitset object. We can use these operations only if the size of the bitset is less than or equal to the corresponding size, unsigned long for to_ulong and unsigned long long for to_ullong:

Click here to view code image

```
unsigned long ulong = bitvec3.to_ulong();
cout << "ulong = " << ulong << endl;</pre>
```

Note

These operations throw an overflow_error exception (§ 5.6, p. 193) if the value in the bitset does not fit in the specified type.

bitset IO Operators

The input operator reads characters from the input stream into a temporary object of type string. It reads until it has read as many characters as the size of the corresponding bitset, or it encounters a character other than 1 or 0, or it encounters end-of-file or an input error. The bitset is then initialized from that temporary string (§ 17.2.1, p. 724). If fewer characters are read than the size of the bitset, the high-order bits are, as usual, set to 0.

The output operator prints the bit pattern in a bitset object:

Click here to view code image

```
bitset<16> bits;
cin >> bits; // read up to 16 1 or 0 characters from cin
cout << "bits: " << bits << endl; // print what we just read</pre>
```

Using bitsets

To illustrate using bitsets, we'll reimplement the grading code from § 4.8 (p. 154) that used an unsigned long to represent the pass/fail quiz results for 30 students:

Click here to view code image

```
bool status;
// version using bitwise operators
unsigned long quizA = 0; // this value is used as a collection of bits
quizA |= 1UL << 27; // indicate student number 27 passed
status = quizA & (1UL << 27); // check how student number 27 did
quizA &= ~(1UL << 27); // student number 27 failed
// equivalent actions using the bitset library
bitset<30> quizB; // allocate one bit per student; all bits initialized to 0
quizB.set(27); // indicate student number 27 passed
status = quizB[27]; // check how student number 27 did
quizB.reset(27); // student number 27 failed
```

Exercises Section 17.2.2

Exercise 17.10: Using the sequence 1, 2, 3, 5, 8, 13, 21, initialize a bitset that has a 1 bit in each position corresponding to a number in this sequence. Default initialize another bitset and write a small program to turn on each of the appropriate bits.

Exercise 17.11: Define a data structure that contains an integral object to track responses to a true/false quiz containing 10 questions. What changes, if

any, would you need to make in your data structure if the quiz had 100 questions?

Exercise 17.12: Using the data structure from the previous question, write a function that takes a question number and a value to indicate a true/false answer and updates the quiz results accordingly.

Exercise 17.13: Write an integral object that contains the correct answers for the true/false quiz. Use it to generate grades on the quiz for the data structure from the previous two exercises.

17.3. Regular Expressions

A **regular expression** is a way of describing a sequence of characters. Regular expressions are a stunningly powerful computational device. However, describing the languages used to define regular expressions is well beyond the scope of this Primer. Instead, we'll focus on how to use the C++ regular-expression library (RE library), which is part of the new library. The RE library, which is defined in the regex header, involves several components, listed in Table 17.4.

Table 17.4. Regular Expression Library Components

Class that represents a regular expression
Matches a sequence of characters against a regular expression
Finds the first subsequence that matches the regular expression
Replaces a regular expression using a given format
Iterator adaptor that calls regex_search to iterate through the matches in a string
Container class that holds the results of searching a string
Results for a matched subexpression in a string

If you are not already familiar with using regular expressions, you might want to skim this section to get an idea of the kinds of things regular expressions can do.

The **regex** class represents a regular expression. Aside from initialization and assignment, regex has few operations. The operations on regex are listed in Table 17.6 (p. 731).

The functions **regex_match** and **regex_search** determine whether a given character sequence matches a given regex. The regex_match function returns true if the

entire input sequence matches the expression; regex_search returns true if there is a substring in the input sequence that matches. There is also a regex_replace function that we'll describe in § 17.3.4 (p. 741).

The arguments to the regex functions are described in Table 17.5 (overleaf). These functions return a bool and are overloaded: One version takes an additional argument of type **smatch**. If present, these functions store additional information about a successful match in the given smatch object.

Table 17.5. Arguments to regex_search and regex_match

```
Note: These operations return bool indicating whether a match was found.

(seq, m, r, mft) Look for the regular expression in the regex object r in the character (seq, r, mft) sequence seq. seq can be a string, a pair of iterators denoting a range, or a pointer to a null-terminated character array.

m is a match object, which is used to hold details about the match.

m and seq must have compatible types (see § 17.3.1 (p. 733)).

mft is an optional regex_constants::match_flag_type value.

These values, listed in Table 17.13 (p. 744), affect the match process.
```

17.3.1. Using the Regular Expression Library

As a fairly simple example, we'll look for words that violate a well-known spelling rule of thumb, "i before e except after c":

Click here to view code image

We start by defining a string to hold the regular expression we want to find. The regular expression [^c] says we want any character that is not a 'c', and [^c]ei says we want any such letter that is followed by the letters ei. This pattern describes strings containing exactly three characters. We want the entire word that contains this pattern. To match the word, we need a regular expression that will match the letters that come before and after our three-letter pattern.

That regular expression consists of zero or more letters followed by our original

three-letter pattern followed by zero or more additional characters. By default, the regular-expression language used by regex objects is ECMAScript. In ECMAScript, the pattern [[:alpha:]] matches any alphabetic character, and the symbols + and * signify that we want "one or more" or "zero or more" matches, respectively. Thus, [[:alpha:]]* will match zero or more characters.

Having stored our regular expression in pattern, we use it to initialize a regex object named r. We next define a string that we'll use to test our regular expression. We initialize test_str with words that match our pattern (e.g., "freind" and "theif") and words (e.g., "receipt" and "receive") that don't. We also define an smatch object named results, which we will pass to regex_search. If a match is found, results will hold the details about where the match occurred.

Next we call regex_search. If regex_search finds a match, it returns true. We use the str member of results to print the part of test_str that matched our pattern. The regex_search function stops looking as soon as it finds a matching substring in the input sequence. Thus, the output will be

freind

§ 17.3.2 (p. 734) will show how to find all the matches in the input.

Specifying Options for a regex Object

When we define a regex or call assign on a regex to give it a new value, we can specify one or more flags that affect how the regex operates. These flags control the processing done by that object. The last six flags listed in Table 17.6 indicate the language in which the regular expression is written. Exactly one of the flags that specify a language must be set. By default, the ECMAScript flag is set, which causes the regex to use the ECMA-262 specification, which is the regular expression language that many Web browsers use.

Table 17.6. regex (and wregex) Operations

```
regex r (re)
                    re represents a regular expression and can be a string, a pair of iterators
regex r(re, f)
                    denoting a range of characters, a pointer to a null-terminated character
                    array, a character pointer and a count, or a braced list of characters. £
                    are flags that specify how the object will execute. f is set from the values
                    listed below. If f is not specified, it defaults to ECMAScript.
                    Replace the regular expression in r1 with re. re represents a regular
r1 = re
                    expression and can be another regex, a string, a pointer to a
                    null-terminated character array, or a braced list of characters.
rl.assign(re, f) Same effect as using the assignment operator (=). re and optional flag f
                    same as corresponding arguments to regex constructors.
r.mark count () Number of subexpressions (which we'll cover in § 17.3.3 (p. 738)) in r.
r.flags()
                    Returns the flags set for r.
Note: Constructors and assignment operations may throw exceptions of type regex error.
                        Flags Specified When a regex Is Defined
          Defined in regex and regex constants::syntax option type
        icase
                        Ignore case during the match
        nosubs
                        Don't store subexpression matches
                        Favor speed of execution over speed of construction
        optimize
        ECMAScript
                        Use grammar as specified by ECMA-262
                        Use POSIX basic regular-expression grammar
        basic
                        Use POSIX extended regular-expression grammar
        extended
        awk
                        Use grammar from the POSIX version of the awk language
                        Use grammar from the POSIX version of grep
        grep
                        Use grammar from the POSIX version of egrep
        egrep
```

The other three flags let us specify language-independent aspects of the regularexpression processing. For example, we can indicate that we want the regular expression to be matched in a case-independent manner.

As one example, we can use the icase flag to find file names that have a particular file extension. Most operating systems recognize extensions in a case-independent manner—we can store a C++ program in a file that ends in .cc, or .cc, or .cc, or .cc, or .cc. We'll write a regular expression to recognize any of these along with other common file extensions as follows:

Click here to view code image

```
// one or more alphanumeric characters followed by a '.' followed by "cpp" or "cxx" or
"cc"
regex r("[[:alnum:]]+\\.(cpp|cxx|cc)$", regex::icase);
smatch results;
string filename;
while (cin >> filename)
   if (regex_search(filename, results, r))
        cout << results.str() << endl; // print the current match</pre>
```

This expression will match a string of one or more letters or digits followed by a period and followed by one of three file extensions. The regular expression will match the file extensions regardless of case.

Just as there are special characters in C++ (§ 2.1.3, p. 39), regular-expression languages typically also have special characters. For example, the dot (.) character usually matches any character. As we do in C++, we can escape the special nature of a character by preceding it with a backslash. Because the backslash is also a special character in C++, we must use a second backslash inside a string literal to indicate to C++ that we want a backslash. Hence, we must write $\setminus \setminus$ to represent a regular expression that will match a period.

Errors in Specifying or Using a Regular Expression

We can think of a regular expression as itself a "program" in a simple programming language. That language is not interpreted by the C++ compiler. Instead, a regular expression is "compiled" at run time when a regex object is initialized with or assigned a new pattern. As with any programming language, it is possible that the regular expressions we write can have errors.

Note

It is important to realize that the syntactic correctness of a regular expression is evaluated at run time.

If we make a mistake in writing a regular expression, then at *run time* the library will throw an exception (§ 5.6, p. 193) of type **regex_error**. Like the standard exception types, regex_error has a what operation that describes the error that occurred (§ 5.6.2, p. 195). A regex_error also has a member named code that returns a numeric code corresponding to the type of error that was encountered. The values code returns are implementation defined. The standard errors that the RE library can throw are listed in Table 17.7.

Table 17.7. Regular Expression Error Conditions

```
Defined in regex and in regex constants::error type
                     Invalid collating element request
error collate
error ctype
                     Invalid character class
error escape
                     Invalid escape character or trailing escape
error backref
                     Invalid back reference
                     Mismatched bracket ([ or ])
error brack
                     Mismatched parentheses (( or ))
error paren
error brace
                     Mismatched brace ({ or })
                     Invalid range inside a { }
error badbrace
                     Invalid character range (e.g., [z-a])
error range
                     Insufficient memory to handle this regular expression
error space
error badrepeat
                     A repetition character (*,?,+,or \{) was not preceded
                     by a valid regular expression
error complexity The requested match is too complex
                     Insufficient memory to evaluate a match
error stack
```

For example, we might inadvertently omit a bracket in a pattern:

Click here to view code image

```
try {
    // error: missing close bracket after alnum; the constructor will throw
    regex r("[[:alnum:]+\\.(cpp|cxx|cc)$", regex::icase);
} catch (regex_error e)
    { cout << e.what() << "\ncode: " << e.code() << endl; }</pre>
```

When run on our system, this program generates

```
regex_error(error_brack):
The expression contained mismatched [ and ].
code: 4
```

Our compiler defines the code member to return the position of the error as listed in Table 17.7, counting, as usual, from zero.

Advice: Avoid Creating Unnecessary Regular Expressions

As we've seen, the "program" that a regular expression represents is compiled at run time, not at compile time. Compiling a regular expression can be a surprisingly slow operation, especially if you're using the extended regular-expression grammar or are using complicated expressions. As a result, constructing a regex object and assigning a new regular expression to an existing regex can be time-consuming. To minimize this overhead, you should try to avoid creating more regex objects than needed. In particular, if you use a regular expression in a loop, you should create it outside the loop rather than recompiling it on each iteration.

We can search any of several types of input sequence. The input can be ordinary char data or wchar_t data and those characters can be stored in a library string or in an array of char (or the wide character versions, wstring or array of wchar_t). The RE library defines separate types that correspond to these differing types of input sequences.

For example, the regex class holds regular expressions of type char. The library also defines a wregex class that holds type wchar_t and has all the same operations as regex. The only difference is that the initializers of a wregex must use wchar_t instead of char.

The match and iterator types (which we will cover in the following sections) are more specific. These types differ not only by the character type, but also by whether the sequence is in a library string or an array: smatch represents string input sequences; cmatch, character array sequences; wsmatch, wide string (wstring) input; and wcmatch, arrays of wide characters.

The important point is that the RE library types we use must match the type of the input sequence. Table 17.8 indicates which types correspond to which kinds of input sequences. For example:

Click here to view code image

Table 17.8. Regular Expression Library Classes

If Input Sequence Has Type	Use Regular Expression Classes
string	regex, smatch, ssub_match, and sregex_iterator
const char*	regex, cmatch, csub_match, and cregex_iterator
wstring	wregex, wsmatch, wssub_match, and wsregex_iterator
const wchar_t*	wregex, wcmatch, wcsub_match, and wcregex_iterator

The (C++) compiler will reject this code because the type of the match argument and the type of the input sequence do not match. If we want to search a character array, then we must use a cmatch object:

Click here to view code image

```
cmatch results; // will match character array input sequences
if (regex_search("myfile.cc", results, r))
    cout << results.str() << endl; // print the current match</pre>
```

In general, our programs will use string input sequences and the corresponding string versions of the RE library components.

Exercises Section 17.3.1

Exercise 17.14: Write several regular expressions designed to trigger various errors. Run your program to see what output your compiler generates for each error.

Exercise 17.15: Write a program using the pattern that finds words that violate the "i before e except after c" rule. Have your program prompt the user to supply a word and indicate whether the word is okay or not. Test your program with words that do and do not violate the rule.

Exercise 17.16: What would happen if your regex object in the previous program were initialized with "[^c]ei"? Test your program using that pattern to see whether your expectations were correct.

17.3.2. The Match and Regex Iterator Types

The program on page 729 that found violations of the "i before e except after c" grammar rule printed only the first match in its input sequence. We can get all the matches by using an **sregex_iterator**. The regex iterators are iterator adaptors (§ 9.6, p. 368) that are bound to an input sequence and a regex object. As described in Table 17.8 (on the previous page), there are specific regex iterator types that correspond to each of the different types of input sequences. The iterator operations are described in Table 17.9 (p. 736).

Table 17.9. sregex_iterator Operations

		lso apply to cregex_iterator, tor, and wcregex_iterator	
sregex_iter		it is an sregx_iterator that iterates through the string denoted by iterators b and e. Calls regex_search(b, e, r) to position it on the first match in the input.	
sregex_iterator end;		Off-the-end iterator for sregex_iterator.	
*it it-> ++it it++	Returns a reference to the smatch object or a pointer to the smatch object from the most recent call to regex_search. Calls regex_search on the input sequence starting just after the current match. The prefix version returns a reference to the incremented iterator postfix returns the old value.		
it1 == it2 it1 != it2		ors are equal if they are both the off-the-end iterator. are equal if they are constructed from the same input object.	

When we bind an sregex_iterator to a string and a regex object, the iterator is automatically positioned on the first match in the given string. That is, the sregex_iterator constructor calls regex_search on the given string and

regex. When we dereference the iterator, we get an smatch object corresponding to the results from the most recent search. When we increment the iterator, it calls regex_search to find the next match in the input string.

Using an sregex_iterator

As an example, we'll extend our program to find all the violations of the "i before e except after c" grammar rule in a file of text. We'll assume that the string named file holds the entire contents of the input file that we want to search. This version of the program will use the same pattern as our original one, but will use a sregex_iterator to do the search:

Click here to view code image

The for loop iterates through each match to r inside file. The initializer in the for defines it and end_it. When we define it, the sregex_iterator constructor calls regex_search to position it on the first match in file. The empty sregex_iterator, end_it, acts as the off-the-end iterator. The increment in the for "advances" the iterator by calling regex_search. When we dereference the iterator, we get an smatch object representing the current match. We call the str member of the match to print the matching word.

We can think of this loop as jumping from match to match as illustrated in Figure 17.1.

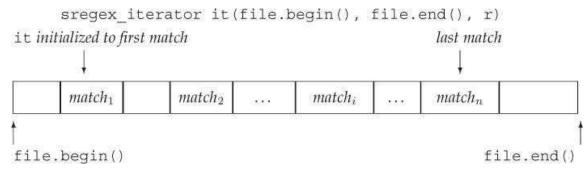

Figure 17.1. Using an sregex_iterator

Using the Match Data

If we run this loop on test_str from our original program, the output would be

freind theif

However, finding just the words that match our expression is not so useful. If we ran the program on a larger input sequence—for example, on the text of this chapter—we'd want to see the context within which the word occurs, such as

Click here to view code image

```
hey read or write according to the type >>> being <<< handled. The input operators ignore whi
```

In addition to letting us print the part of the input string that was matched, the match classes give us more detailed information about the match. The operations on these types are listed in Table 17.10 (p. 737) and Table 17.11 (p. 741).

Table 17.10. smatch Operations

	perations also apply to the cmatch, wsmatch, wcmatch and the onding csub_match, wssub_match, and wcsub_match types.		
m.ready()	true if m has been set by a call to regex_search or regex_match; false otherwise. Operations on m are undefined if ready returns false.		
m.size()	Zero if the match failed; otherwise, one plus the number of subexpressions in the most recently matched regular expression.		
m.empty()	true if m.size() is zero.		
m.prefix()	An ssub_match representing the sequence before the match.		
m.suffix()	An ssub_match representing the part after the end of the match.		
m.format()	See Table 17.12 (p. 742).		
and the second control of the second of the	that take an index, n defaults to zero and must be less than ${\tt m.size}$ (). submatch (the one with index 0) represents the overall match.		
m.length(n)	Size of the nth matched subexpression.		
m.position(n)	Distance of the nth subexpression from the start of the sequence.		
m.str(n)	The matched string for the nth subexpression.		
m[n]	ssub_match object corresponding to the nth subexpression.		
m.begin(), m.e m.cbegin(), m.	(사용하게 하게		

Table 17.11. Submatch Operations

```
Note: These operations apply to ssub match, csub match, wssub match, wcsub match
             A public bool data member that indicates whether this ssub match was
matched
             matched.
             public data members that are iterators to the start and one past the end of the
first
second
             matching sequence. If there was no match, then first and second are equal.
            The size of this match. Returns 0 if matched is false.
length()
            Returns a string containing the matched portion of the input. Returns the
str()
             empty string if matched is false.
            Convert the ssub match object ssub to the string s. Equivalent to s =
s = ssub
             ssub.str(). The conversion operator is not explicit (§ 14.9.1, p. 581).
```

We'll have more to say about the smatch and ssub_match types in the next section. For now, what we need to know is that these types let us see the context of a match. The match types have members named prefix and suffix, which return a ssub_match object representing the part of the input sequence ahead of and after the current match, respectively. A ssub_match object has members named str and length, which return the matched string and size of that string, respectively. We can use these operations to rewrite the loop of our grammar program:

Click here to view code image

The loop itself operates the same way as our previous program. What's changed is the processing inside the for, which is illustrated in Figure 17.2.

```
it->str()
when it refers to the ith smatch object

it->str()

xxxeixxx it->suffix().str()
```

Figure 17.2. The smatch Object Representing a Particular Match

We call prefix, which returns an ssub_match object that represents the part of

file ahead of the current match. We call length on that ssub_match to find out how many characters are in the part of file ahead of the match. Next we adjust pos to be the index of the character 40 from the end of the prefix. If the prefix has fewer than 40 characters, we set pos to 0, which means we'll print the entire prefix. We use substr (§ 9.5.1, p. 361) to print from the given position to the end of the prefix.

Having printed the characters that precede the match, we next print the match itself with some additional formatting so that the matched word will stand out in the output. After printing the matched portion, we print (up to) the first 40 characters in the part of file that comes after this match.

Exercises Section 17.3.2

Exercise 17.17: Update your program so that it finds all the words in an input sequence that violiate the "ei" grammar rule.

Exercise 17.18: Revise your program to ignore words that contain "ei" but are not misspellings, such as "albeit" and "neighbor."

17.3.3. Using Subexpressions

A pattern in a regular expression often contains one or more **subexpressions**. A subexpression is a part of the pattern that itself has meaning. Regular-expression grammars typically use parentheses to denote subexpressions.

As an example, the pattern that we used to match C++ files (§ 17.3.1, p. 730) used parentheses to group the possible file extensions. Whenever we group alternatives using parentheses, we are also declaring that those alternatives form a subexpression. We can rewrite that expression so that it gives us access to the file name, which is the part of the pattern that precedes the period, as follows:

Click here to view code image

```
// r has two subexpressions: the first is the part of the file name before the period 
// the second is the file extension 
regex r("([[:alnum:]]+)\\.(cpp|cxx|cc)$", regex::icase);
```

Our pattern now has two parenthesized subexpressions:

- ([[:alnum:]]+), which is a sequence of one or more characters
- (cpp \mid cxx \mid cc), which is the file extension

We can also rewrite the program from § 17.3.1 (p. 730) to print just the file name by changing the output statement:

Click here to view code image

```
if (regex_search(filename, results, r))
```

```
cout << results.str(1) << endl; // print the first subexpression</pre>
```

As in our original program, we call $regex_search$ to look for our pattern r in the string named filename, and we pass the smatch object results to hold the results of the match. If the call succeeds, then we print the results. However, in this program, we print str(1), which is the match for the first subexpression.

In addition to providing information about the overall match, the match objects provide access to each matched subexpression in the pattern. The submatches are accessed positionally. The first submatch, which is at position 0, represents the match for the entire pattern. Each subexpression appears in order thereafter. Hence, the file name, which is the first subexpression in our pattern, is at position 1, and the file extension is in position 2.

For example, if the file name is foo.cpp, then results.str(0) will hold foo.cpp; results.str(1) will be foo; and results.str(2) will be cpp. In this program, we want the part of the name before the period, which is the first subexpression, so we print results.str(1).

Subexpressions for Data Validation

One common use for subexpressions is to validate data that must match a specific format. For example, U.S. phone numbers have ten digits, consisting of an area code and a seven-digit local number. The area code is often, but not always, enclosed in parentheses. The remaining seven digits can be separated by a dash, a dot, or a space; or not separated at all. We might want to allow data with any of these formats and reject numbers in other forms. We'll do a two-step process: First, we'll use a regular expression to find sequences that might be phone numbers and then we'll call a function to complete the validation of the data.

Before we write our phone number pattern, we need to describe a few more aspects of the ECMAScript regular-expression language:

- $\{d\}$ represents a single digit and $\{d\}\{n\}$ represents a sequence of n digits. (E.g., $\{d\}\{3\}$ matches a sequence of three digits.)
- A collection of characters inside square brackets allows a match to any of those characters. (E.g., [.] matches a dash, a dot, or a space. Note that a dot has no special meaning inside brackets.)
- A component followed by '?' is optional. (E.g., \d { 3 } [.]? \d { 4 } matches three digits followed by an optional dash, period, or space, followed by four more digits. This pattern would match 555-0132 or 555.0132 or 555 0132 or 5550132.)
- Like C++, ECMAScript uses a backslash to indicate that a character should represent itself, rather than its special meaning. Because our pattern includes parentheses, which are special characters in ECMAScript, we must represent the parentheses that are part of our pattern as \(()()).

Because backslash is a special character in C++, each place that a \ appears in the pattern, we must use a second backslash to indicate to C++ that we want a backslash. Hence, we write $\{d\}\{3\}$ to represent the regular expression $\{d\}\{3\}$.

In order to validate our phone numbers, we'll need access to the components of the pattern. For example, we'll want to verify that if a number uses an opening parenthesis for the area code, it also uses a close parenthesis after the area code. That is, we'd like to reject a number such as (908.555.1800.

To get at the components of the match, we need to define our regular expression using subexpressions. Each subexpression is marked by a pair of parentheses:

Click here to view code image

```
// our overall expression has seven subexpressions: ( ddd ) separator ddd separator dddd // subexpressions 1, 3, 4, and 6 are optional; 2, 5, and 7 hold the number "(\\()?(\\d{3})(\\))?([-.])?(\\d{3})([-.]?)(\\d{4})";
```

Because our pattern uses parentheses, and because we must escape backslashes, this pattern can be hard to read (and write!). The easiest way to read it is to pick off each (parenthesized) subexpression:

- **1.** (\\()? an optional open parenthesis for the area code
- **2.** $(\d{3})$ the area code
- **3.** (\\))? an optional close parenthesis for the area code
- **4.** ([-.])? an optional separator after the area code
- **5.** (\\d{3}) the next three digits of the number
- **6.** ([-.])? another optional separator
- **7.** $(\d{4})$ the final four digits of the number

The following code uses this pattern to read a file and find data that match our overall phone pattern. It will call a function named valid to check whether the number has a valid format:

Click here to view code image

Using the Submatch Operations

We'll use submatch operations, which are outlined in Table 17.11, to write the valid function. It is important to keep in mind that our pattern has seven subexpressions. As a result, each smatch object will contain eight ssub_match elements. The element at [0]represents the overall match; the elements [1]...[7] represent each of the corresponding subexpressions.

When we call valid, we know that we have an overall match, but we do not know which of our optional subexpressions were part of that match. The matched member of the ssub_match corresponding to a particular subexpression is true if that subexpression is part of the overall match.

In a valid phone number, the area code is either fully parenthesized or not parenthesized at all. Therefore, the work valid does depends on whether the number starts with a parenthesis or not:

Click here to view code image

```
bool valid(const smatch& m)
{
    // if there is an open parenthesis before the area code
    if(m[1].matched)
        // the area code must be followed by a close parenthesis
        // and followed immediately by the rest of the number or a space
        return m[3].matched
        && (m[4].matched == 0 || m[4].str() == " ");
    else
        // then there can't be a close after the area code
        // the delimiters between the other two components must match
        return !m[3].matched
        && m[4].str() == m[6].str();
}
```

We start by checking whether the first subexpression (i.e., the open parenthesis) matched. That subexpression is in $\mathfrak{m}[1]$. If it matched, then the number starts with an open parenthesis. In this case, the overall number is valid if the subexpression following the area code also matched (meaning that there was a close parenthesis after the area code). Moreover, if the number is correctly parenthesized, then the next character must be a space or the first digit in the next part of the number.

If m[1] didn't match (i.e., there was no open parenthesis), the subexpression following the area code must also be empty. If it's empty, then the number is valid if the remaining separators are equal and not otherwise.

Exercises Section 17.3.3

Exercise 17.19: Why is it okay to call m[4].str() without first checking whether m[4] was matched?

Exercise 17.20: Write your own version of the program to validate phone numbers.

Exercise 17.21: Rewrite your phone number program from § 8.3.2 (p. 323) to use the valid function defined in this section.

Exercise 17.22: Rewrite your phone program so that it allows any number of whitespace characters to separate the three parts of a phone number.

Exercise 17.23: Write a regular expression to find zip codes. A zip code can have five or nine digits. The first five digits can be separated from the remaining four by a dash.

17.3.4. Using regex_replace

Regular expressions are often used when we need not only to find a given sequence but also to replace that sequence with another one. For example, we might want to translate U.S. phone numbers into the form "ddd.ddd.dddd," where the area code and next three digits are separated by a dot.

When we want to find and replace a regular expression in the input sequence, we call **regex_replace**. Like the search functions, regex_replace, which is described in Table 17.12, takes an input character sequence and a regex object. We must also pass a string that describes the output we want.

Table 17.12. Regular Expression Replace Operations

```
m.format(fmt, mft)
```

m. format (dest, fmt, mft) Produces formatted output using the format string fmt, the match in m, and the optional match flag type flags in mft. The first version writes to the output iterator dest (§ 10.5.1, p. 410) and takes fmt that is either a string or a pair of pointers denoting a range in a character array. The second version returns a string that holds the output and takes fmt that is a string or a pointer to a null-terminated character array. mft defaults to format default.

```
regex replace
(dest, seq, r, fmt, mft)
regex replace
(seq, r, fmt, mft)
```

Iterates through seq, using regex search to find successive matches to regex r. Uses the format string fmt and optional match flag type flags in mft to produce its output. The first version writes to the output iterator dest, and takes a pair of iterators to denote seq. The second returns a string that holds the output and seq can be either a string or a pointer to a null-terminated character array. In all cases, fmt can be either a string or a pointer to a null-terminated character array, and mft defaults to match default.

We compose a replacement string by including the characters we want, intermixed with subexpressions from the matched substring. In this case, we want to use the second, fifth, and seventh subexpressions in our replacement string. We'll ignore the first, third, fourth, and sixth, because these were used in the original formatting of the number but are not part of our replacement format. We refer to a particular subexpression by using a \$ symbol followed by the index number for a subexpression:

Click here to view code image

```
string fmt = "$2.$5.$7"; // reformat numbers to ddd.ddd.dddd
```

We can use our regular-expression pattern and the replacement string as follows:

Click here to view code image

```
regex r(phone); // a regex to find our pattern
string number = "(908) 555-1800";
cout << regex_replace(number, r, fmt) << endl;</pre>
```

The output from this program is

908.555.1800

Replacing Only Part of the Input Sequence

A more interesting use of our regular-expression processing would be to replace phone numbers that are embedded in a larger file. For example, we might have a file of names and phone number that had data like this:

Click here to view code image

morgan (201) 555-2368 862-555-0123

```
drew (973)555.0130
lee (609) 555-0132 2015550175 800.555-0000
```

that we want to transform to data like this:

Click here to view code image

```
morgan 201.555.2368 862.555.0123
drew 973.555.0130
lee 609.555.0132 201.555.0175 800.555.0000
```

We can generate this transformation with the following program:

Click here to view code image

We read each record into s and hand that record to regex_replace. This function finds and transforms all the matches in its input sequence.

Flags to Control Matches and Formatting

Just as the library defines flags to direct how to process a regular expression, the library also defines flags that we can use to control the match process or the formatting done during a replacement. These values are listed in Table 17.13 (overleaf). These flags can be passed to the regex_search or regex_match functions or to the format members of class smatch.

Table 17.13. Match Flags

Defined in regex constants::match flag type Equivalent to format default match default Don't treat the first character as the beginning of the line match not bol match not eol Don't treat the last character as the end of the line match not bow Don't treat the first character as the beginning of a word Don't treat the last character as the end of a word match not eow If there is more than one match, any match can be returned match any match not null Don't match an empty sequence The match must begin with the first character in the input match continuous The input sequence has characters before the first match prev avail format default Replacement string uses the ECMAScript rules Replacement string uses the rules from POSIX sed format sed Don't output the unmatched parts of the input format no copy format first only Replace only the first occurrence

The match and format flags have type match_flag_type. These values are defined in a namespace named regex_constants. Like placeholders, which we used with bind (§ 10.3.4, p. 399), regex_constants is a namespace defined inside the std namespace. To use a name from regex_constants, we must qualify that name with the names of both namespaces:

Click here to view code image

```
using std::regex_constants::format_no_copy;
```

This declaration says that when our code uses format_no_copy, we want the object of that name from the namespace std::regex_constants. We can instead provide the alternative form of using that we will cover in § 18.2.2 (p. 792):

Click here to view code image

```
using namespace std::regex_constants;
```

Using Format Flags

By default, regex_replace outputs its entire input sequence. The parts that don't match the regular expression are output without change; the parts that do match are formatted as indicated by the given format string. We can change this default behavior by specifying format_no_copy in the call to regex_replace:

Click here to view code image

```
// generate just the phone numbers: use a new format string
string fmt2 = "$2.$5.$7 "; // put space after the last number as a separator
// tell regex_replace to copy only the text that it replaces
cout << regex_replace(s, r, fmt2, format_no_copy) << endl;</pre>
```

Given the same input, this version of the program generates

Click here to view code image

201.555.2368 862.555.0123 973.555.0130 609.555.0132 201.555.0175 800.555.0000

Exercises Section 17.3.4

Exercise 17.24: Write your own version of the program to reformat phone numbers.

Exercise 17.25: Rewrite your phone program so that it writes only the first phone number for each person.

Exercise 17.26: Rewrite your phone program so that it writes only the second and subsequent phone numbers for people with more than one phone number.

Exercise 17.27: Write a program that reformats a nine-digit zip code as ddddd-dddd.

17.4. Random Numbers

Programs often need a source of random numbers. Prior to the new standard, both C and C++ relied on a simple C library function named rand. That function produces pseudorandom integers that are uniformly distributed in the range from 0 to a system-dependent maximum value that is at least 32767.

The rand function has several problems: Many, if not most, programs need random numbers in a different range from the one produced by rand. Some applications require random floating-point numbers. Some programs need numbers that reflect a nonuniform distribution. Programmers often introduce nonrandomness when they try to transform the range, type, or distribution of the numbers generated by rand.

The random-number library, defined in the random header, solves these problems through a set of cooperating classes: random-number engines and random-number distribution classes. These clases are described in Table 17.14. An engine generates a sequence of unsigned random numbers. A distribution uses an engine to generate random numbers of a specified type, in a given range, distributed according to a particular probability distribution.

Table 17.14. Random Number Library Components

Engine Types that generate a sequence of random unsigned integers
Distribution Types that use an engine to return numbers according to a
particular probability distribution

* Best Practices

C++ programs should not use the library rand function. Instead, they should use the default_random_engine along with an appropriate distribution object.

17.4.1. Random-Number Engines and Distribution

The random-number engines are function-object classes (§ 14.8, p. 571) that define a call operator that takes no arguments and returns a random unsigned number. We can generate raw random numbers by calling an object of a random-number engine type:

Click here to view code image

```
default_random_engine e; // generates random unsigned integers
for (size_t i = 0; i < 10; ++i)
    // e() "calls" the object to produce the next random number
    cout << e() << " ";</pre>
```

On our system, this program generates:

Click here to view code image

```
16807 282475249 1622650073 984943658 1144108930 470211272 ...
```

Here, we defined an object named e that has type **default_random_engine**. Inside the for, we call the object e to obtain the next random number.

The library defines several random-number engines that differ in terms of their performance and quality of randomness. Each compiler designates one of these engines as the default_random_engine type. This type is intended to be the engine with the most generally useful properties. Table 17.15 lists the engine operations and the engine types defined by the standard are listed in § A.3.2 (p. 884).

Table 17.15. Random Number Engine Operations

```
Engine e; Default constructor; uses the default seed for the engine type

Engine e(s); Uses the integral value s as the seed
e.seed(s) Reset the state of the engine using the seed s
e.min() The smallest and largest numbers this generator will generate
e.max()
Engine::result_type The unsigned integral type this engine generates
e.discard(u) Advance the engine by u steps; u has type unsigned long long
```

For most purposes, the output of an engine is not directly usable, which is why we

described them earlier as raw random numbers. The problem is that the numbers usually span a range that differs from the one we need. Correctly transforming the range of a random number is surprisingly hard.

Distribution Types and Engines

To get a number in a specified range, we use an object of a distribution type:

Click here to view code image

```
// uniformly distributed from 0 to 9 inclusive
uniform_int_distribution<unsigned> u(0,9);
default_random_engine e; // generates unsigned random integers
for (size_t i = 0; i < 10; ++i)
     // u uses e as a source of numbers
     // each call returns a uniformly distributed value in the specified range
     cout << u(e) << " ";
```

This code produces output such as

```
0174520669
```

Here we define u as a uniform_int_distribution<unsigned>. That type generates uniformly distributed unsigned values. When we define an object of this type, we can supply the minimum and maximum values we want. In this program, u(0,9) says that we want numbers to be in the range 0 to 9 inclusive. The random number distributions use inclusive ranges so that we can obtain every possible value of the given integral type.

Like the engine types, the distribution types are also function-object classes. The distribution types define a call operator that takes a random-number engine as its argument. The distribution object uses its engine argument to produce random numbers that the distribution object maps to the specified distribution.

Note that we pass the engine object itself, u(e). Had we written the call as u(e()), we would have tried to pass the next value generated by e to u, which would be a compile-time error. We pass the engine, not the next result of the engine, because some distributions may need to call the engine more than once.

When we refer to a random-number generator, we mean the combination of a distribution object with an engine.

Comparing Random Engines and the rand Function

For readers familiar with the C library rand function, it is worth noting that the output of calling a default_random_engine object is similar to the output of rand. Engines deliver unsigned integers in a system-defined range. The range for rand is 0 to RAND_MAX. The range for an engine type is returned by calling the min and max members on an object of that type:

Click here to view code image

```
cout << "min: " << e.min() << " max: " << e.max() << endl;</pre>
```

On our system this program produces the following output:

min: 1 max: 2147483646

Engines Generate a Sequence of Numbers

Random number generators have one property that often confuses new users: Even though the numbers that are generated appear to be random, a given generator returns the same sequence of numbers each time it is run. The fact that the sequence is unchanging is very helpful during testing. On the other hand, programs that use random-number generators have to take this fact into account.

As one example, assume we need a function that will generate a vector of 100 random integers uniformly distributed in the range from 0 to 9. We might think we'd write this function as follows:

Click here to view code image

```
// almost surely the wrong way to generate a vector of random integers
// output from this function will be the same 100 numbers on every call!
vector<unsigned> bad_randVec()
{
    default_random_engine e;
    uniform_int_distribution<unsigned> u(0,9);
    vector<unsigned> ret;
    for (size_t i = 0; i < 100; ++i)
        ret.push_back(u(e));
    return ret;
}</pre>
```

However, this function will return the same vector every time it is called:

Click here to view code image

```
vector<unsigned> v1(bad_randVec());
vector<unsigned> v2(bad_randVec());
// will print equal
cout << ((v1 == v2) ? "equal" : "not equal") << endl;</pre>
```

This code will print equal because the vectors v1 and v2 have the same values.

The right way to write our function is to make the engine and associated

distribution objects static (§ 6.1.1, p. 205):

Click here to view code image

```
// returns a vector of 100 uniformly distributed random numbers
vector<unsigned> good_randVec()
     // because engines and distributions retain state, they usually should be
     // defined as static so that new numbers are generated on each call
    static default_random_engine e;
    static uniform_int_distribution<unsigned> u(0,9);
    vector<unsigned> ret;
    for (size_t i = 0; i < 100; ++i)
         ret.push_back(u(e));
    return ret;
```

Because e and u are static, they will hold their state across calls to the function. The first call will use the first 100 random numbers from the sequence u(e) generates, the second call will get the next 100, and so on.

A given random-number generator always produces the same sequence of numbers. A function with a local random-number generator should make that generator (both the engine and distribution objects) static. Otherwise, the function will generate the identical sequence on each call.

Seeding a Generator

The fact that a generator returns the same sequence of numbers is helpful during debugging. However, once our program is tested, we often want to cause each run of the program to generate different random results. We do so by providing a seed. A seed is a value that an engine can use to cause it to start generating numbers at a new point in its sequence.

We can seed an engine in one of two ways: We can provide the seed when we create an engine object, or we can call the engine's seed member:

```
// uses the default seed
default random engine e1;
default random engine e2(2147483646); // use the given seed value
// e3 and e4 will generate the same sequence because they use the same seed
default random engine e3;
                                       // uses the default seed value
e3.seed(32767);
                                        // call seed to set a new seed value
default_random_engine e4(32767); // set the seed value to 32767
```

```
for (size_t i = 0; i != 100; ++i) {
    if (e1() == e2())
           cout << "unseeded match at iteration: " << i <<</pre>
endl;
    if (e3() != e4())
           cout << "seeded differs at iteration: " << i <<</pre>
endl;
```

Here we define four engines. The first two, e1 and e2, have different seeds and should generate different sequences. The second two, e3 and e4, have the same seed value. These two objects will generate the same sequence.

Picking a good seed, like most things about generating good random numbers, is surprisingly hard. Perhaps the most common approach is to call the system time function. This function, defined in the ctime header, returns the number of seconds since a given epoch. The time function takes a single parameter that is a pointer to a structure into which to write the time. If that pointer is null, the function just returns the time:

Click here to view code image

```
default_random_engine e1(time(0)); // a somewhat random seed
```

Because time returns time as the number of seconds, this seed is useful only for applications that generate the seed at second-level, or longer, intervals.

Warning

Using time as a seed usually doesn't work if the program is run repeatedly as part of an automated process; it might wind up with the same seed several times.

Exercises Section 17.4.1

Exercise 17.28: Write a function that generates and returns a uniformly distributed random unsigned inteach time it is called.

Exercise 17.29: Allow the user to supply a seed as an optional argument to the function you wrote in the previous exercise.

Exercise 17.30: Revise your function again this time to take a minimum and maximum value for the numbers that the function should return.

17.4.2. Other Kinds of Distributions

The engines produce unsigned numbers, and each number in the engine's range has

the same likelihood of being generated. Applications often need numbers of different types or distributions. The library handles both these needs by defining different distributions that, when used with an engine, produce the desired results. Table 17.16 (overleaf) lists the operations supported by the distribution types.

Table 17.16. Distribution Operations

Dist d;	Default constructor; makes d ready to use.
	Other constructors depend on the type of Dist; see § A.3 (p. 882).
	The distribution constructors are explicit (§ 7.5.4, p. 296).
d(e)	Successive calls with the same e produce a sequence of random numbers according to the distribution type of d; e is a random-number engine object.
d.min() d.max()	Return the smallest and largest numbers d (e) will generate.
d.reset()	Reestablish the state of d so that subsequent uses of d don't depend on values of
	has already generated.

Generating Random Real Numbers

Programs often need a source of random floating-point values. In particular, programs frequently need random numbers between zero and one.

The most common, but incorrect, way to obtain a random floating-point from rand is to divide the result of rand() by RAND_MAX, which is a system-defined upper limit that is the largest random number that rand can return. This technique is incorrect because random integers usually have less precision than floating-point numbers, in which case there are some floating-point values that will never be produced as output.

With the new library facilities, we can easily obtain a floating-point random number. We define an object of type uniform_real_distribution and let the library handle mapping random integers to random floating-point numbers. As we did for uniform_int_distribution, we specify the minimum and maximum values when we define the object:

Click here to view code image

This code is nearly identical to the previous program that generated unsigned values. However, because we used a different distribution type, this version generates different results:

0.131538 0.45865 0.218959 0.678865 0.934693 0.519416 ...

Using the Distribution's Default Result Type

With one exception, which we'll cover in § 17.4.2 (p. 752), the distribution types are templates that have a single template type parameter that represents the type of the numbers that the distribution generates. These types always generate either a floating-point type or an integral type.

Each distribution template has a default template argument (§ 16.1.3, p. 670). The distribution types that generate floating-point values generate double by default. Distributions that generate integral results use int as their default. Because the distribution types have only one template parameter, when we want to use the default we must remember to follow the template's name with empty angle brackets to signify that we want the default (§ 16.1.3, p. 671):

Click here to view code image

```
// empty <> signify we want to use the default result type
uniform_real_distribution<> u(0,1); // generates double by default
```

Generating Numbers That Are Not Uniformly Distributed

In addition to correctly generating numbers in a specified range, another advantage of the new library is that we can obtain numbers that are nonuniformly distributed. Indeed, the library defines 20 distribution types! These types are listed in § A.3 (p. 882).

As an example, we'll generate a series of normally distributed values and plot the resulting distribution. Because normal_distribution generates floating-point numbers, our program will use the lround function from the cmath header to round each result to its nearest integer. We'll generate 200 numbers centered around a mean of 4 with a standard deviation of 1.5. Because we're using a normal distribution, we can expect all but about 1 percent of the generated numbers to be in the range from 0 to 8, inclusive. Our program will count how many values appear that map to the integers in this range:

```
for (size_t j = 0; j != vals.size(); ++j)
    cout << j << ": " << string(vals[j], '*') << endl;</pre>
```

We start by defining our random generator objects and a vector named vals. We'll use vals to count how often each number in the range 0 . . . 9 occurs. Unlike most of our programs that use vector, we allocate vals at its desired size. By doing so, we start out with each element initialized to 0.

Inside the for loop, we call lround(n(e)) to round the value returned by n(e) to the nearest integer. Having obtained the integer that corresponds to our floating-point random number, we use that number to index our vector of counters. Because n(e) can produce a number outside the range 0 to 9, we check that the number we got is in range before using it to index vals. If the number is in range, we increment the associated counter.

When the loop completes, we print the contents of vals, which will generate output such as

Click here to view code image

Here we print a string with as many asterisks as the count of the times the current value was returned by our random-number generator. Note that this figure is not perfectly symmetrical. If it were, that symmetry should give us reason to suspect the quality of our random-number generator.

The bernoulli distribution Class

We noted that there was one distribution that does not take a template parameter. That distribution is the bernoulli_distribution, which is an ordinary class, not a template. This distribution always returns a bool value. It returns true with a given probability. By default that probability is .5.

As an example of this kind of distribution, we might have a program that plays a game with a user. To play the game, one of the players—either the user or the program—has to go first. We could use a uniform_int_distribution object with a range of 0 to 1 to select the first player. Alternatively, we can use a Bernoulli distribution to make this choice. Assuming that we have a function named play that plays the game, we might have a loop such as the following to interact with the user:

Click here to view code image

We use a do while (§ 5.4.4, p. 189) to repeatedly prompt the user to play.

Warning

Because engines return the same sequence of numbers (§ 17.4.1, p. 747), it is essential that we declare engines outside of loops. Otherwise, we'd create a new engine on each iteration and generate the same values on each iteration. Similarly, distributions may retain state and should also be defined outside loops.

One reason to use a bernoulli_distribution in this program is that doing so lets us give the program a better chance of going first:

Click here to view code image

```
bernoulli_distribution b(.55); // give the house a slight edge
```

If we use this definition for b, then the program has 55/45 odds of going first.

17.5. The IO Library Revisited

In Chapter 8 we introduced the basic architecture and most commonly used parts of the IO library. In this section we'll look at three of the more specialized features that the IO library supports: format control, unformatted IO, and random access.

Exercises Section 17.4.2

Exercise 17.31: What would happen if we defined b and e inside the do loop of the game-playing program from this section?

Exercise 17.32: What would happen if we defined resp inside the loop?

Exercise 17.33: Write a version of the word transformation program from § 11.3.6 (p. 440) that allows multiple transformations for a given word and randomly selects which transformation to apply.

17.5.1. Formatted Input and Output

In addition to its condition state (§ 8.1.2, p. 312), each iostream object also maintains a format state that controls the details of how IO is formatted. The format state controls aspects of formatting such as the notational base for integral values, the precision of floating-point values, the width of an output element, and so on.

The library defines a set of **manipulators** (§ 1.2, p. 7), listed in Tables 17.17 (p. 757) and 17.18 (p. 760), that modify the format state of a stream. A manipulator is a function or object that affects the state of a stream and can be used as an operand to an input or output operator. Like the input and output operators, a manipulator returns the stream object to which it is applied, so we can combine manipulators and data in a single statement.

Our programs have already used one manipulator, end1, which we "write" to an output stream as if it were a value. But end1 isn't an ordinary value; instead, it performs an operation: It writes a newline and flushes the buffer.

Many Manipulators Change the Format State

Manipulators are used for two broad categories of output control: controlling the presentation of numeric values and controlling the amount and placement of padding. Most of the manipulators that change the format state provide set/unset pairs; one manipulator sets the format state to a new value and the other unsets it, restoring the normal default formatting.

Warning

Manipulators that change the format state of the stream usually leave the format state changed for all subsequent IO.

The fact that a manipulator makes a persistent change to the format state can be useful when we have a set of IO operations that want to use the same formatting. Indeed, some programs take advantage of this aspect of manipulators to reset the behavior of one or more formatting rules for all its input or output. In such cases, the fact that a manipulator changes the stream is a desirable property.

However, many programs (and, more importantly, programmers) expect the state of the stream to match the normal library defaults. In these cases, leaving the state of

the stream in a nonstandard state can lead to errors. As a result, it is usually best to undo whatever state changes are made as soon as those changes are no longer needed.

Controlling the Format of Boolean Values

One example of a manipulator that changes the formatting state of its object is the boolalpha manipulator. By default, bool values print as 1 or 0. A true value is written as the integer 1 and a false value as 0. We can override this formatting by applying the boolalpha manipulator to the stream:

Click here to view code image

When executed, this program generates the following:

Click here to view code image

default bool values: 1 0 alpha bool values: true false

Once we "write" boolalpha on cout, we've changed how cout will print bool values from this point on. Subsequent operations that print bools will print them as either true or false.

To undo the format state change to cout, we apply noboolalpha:

Click here to view code image

Here we change the format of bool values only to print the value of bool_val. Once that value is printed, we immediately reset the stream back to its initial state.

Specifying the Base for Integral Values

By default, integral values are written and read in decimal notation. We can change the notational base to octal or hexadecimal or back to decimal by using the manipulators hex, oct, and dec:

```
cout << "default: " << 20 << " " << 1024 << endl;
cout << "octal: " << oct << 20 << " " << 1024 << endl;
cout << "hex: " << hex << 20 << " " << 1024 << endl;</pre>
```

```
cout << "decimal: " << dec << 20 << " " << 1024 << endl;
```

When compiled and executed, this program generates the following output:

default: 20 1024 octal: 24 2000 hex: 14 400 decimal: 20 1024

Notice that like boolalpha, these manipulators change the format state. They affect the immediately following output and all subsequent integral output until the format is reset by invoking another manipulator.

Note

The hex, oct, and dec manipulators affect only integral operands; the representation of floating-point values is unaffected.

Indicating Base on the Output

By default, when we print numbers, there is no visual cue as to what notational base was used. Is 20, for example, really 20, or an octal representation of 16? When we print numbers in decimal mode, the number is printed as we expect. If we need to print octal or hexadecimal values, it is likely that we should also use the showbase manipulator. The showbase manipulator causes the output stream to use the same conventions as used for specifying the base of an integral constant:

- A leading 0x indicates hexadecimal.
- A leading 0 indicates octal.
- The absence of either indicates decimal.

Here we've revised the previous program to use showbase:

Click here to view code image

The revised output makes it clear what the underlying value really is:

default: 20 1024 in octal: 024 02000 in hex: 0x14 0x400

in decimal: 20 1024

The noshowbase manipulator resets cout so that it no longer displays the notational base of integral values.

By default, hexadecimal values are printed in lowercase with a lowercase x. We can display the x and the hex digits a-f as uppercase by applying the uppercase manipulator:

Click here to view code image

This statement generates the following output:

printed in hexadecimal: 0X14 0X400

We apply the nouppercase, noshowbase, and dec manipulators to return the stream to its original state.

Controlling the Format of Floating-Point Values

We can control three aspects of floating-point output:

- · How many digits of precision are printed
- Whether the number is printed in hexadecimal, fixed decimal, or scientific notation
- Whether a decimal point is printed for floating-point values that are whole numbers

By default, floating-point values are printed using six digits of precision; the decimal point is omitted if the value has no fractional part; and they are printed in either fixed decimal or scientific notation depending on the value of the number. The library chooses a format that enhances readability of the number. Very large and very small values are printed using scientific notation. Other values are printed in fixed decimal.

Specifying How Much Precision to Print

By default, precision controls the total number of digits that are printed. When printed, floating-point values are rounded, not truncated, to the current precision. Thus, if the current precision is four, then 3.14159 becomes 3.142; if the precision is three, then it is printed as 3.14.

We can change the precision by calling the precision member of an IO object or by using the setprecision manipulator. The precision member is overloaded (§ 6.4, p. 230). One version takes an int value and sets the precision to that new value. It returns the *previous* precision value. The other version takes no arguments and

returns the current precision value. The setprecision manipulator takes an argument, which it uses to set the precision.

Note

The setprecision manipulators and other manipulators that take arguments are defined in the iomanip header.

The following program illustrates the different ways we can control the precision used to print floating-point values:

Click here to view code image

When compiled and executed, the program generates the following output:

Click here to view code image

Precision: 6, Value: 1.41421

Precision: 12, Value: 1.41421356237

Precision: 3, Value: 1.41

Table 17.17. Manipulators Defined in iostream

	boolalpha	Display true and false as strings
*	noboolalpha	Display true and false as 0, 1
	showbase	Generate prefix indicating the numeric base of integral values
*	noshowbase	Do not generate notational base prefix
	showpoint	Always display a decimal point for floating-point values
*	noshowpoint	Display a decimal point only if the value has a fractional part
	showpos	Display + in nonnegative numbers
*	noshowpos	Do not display + in nonnegative numbers
	uppercase	Print OX in hexadecimal, E in scientific
*	nouppercase	Print 0x in hexadecimal, e in scientific
*	dec	Display integral values in decimal numeric base
	hex	Display integral values in hexadecimal numeric base
	oct	Display integral values in octal numeric base
	left	Add fill characters to the right of the value
	right	Add fill characters to the left of the value
	internal	Add fill characters between the sign and the value
	fixed	Display floating-point values in decimal notation
	scientific	Display floating-point values in scientific notation
	hexfloat	Display floating-point values in hex (new to C++ 11)
	defaultfloat	Reset the floating-point format to decimal (new to C++ 11)
	unitbuf	Flush buffers after every output operation
*	nounitbuf	Restore normal buffer flushing
华	skipws	Skip whitespace with input operators
	noskipws	Do not skip whitespace with input operators
	flush	Flush the ostream buffer
	ends	Insert null, then flush the ostream buffer
	endl	Insert newline, then flush the ostream buffer

This program calls the library sgrt function, which is found in the cmath header. The sgrt function is overloaded and can be called on either a float, double, or long double argument. It returns the square root of its argument.

Specifying the Notation of Floating-Point Numbers

Best Practices

Unless you need to control the presentation of a floating-point number (e.g., to print data in columns or to print data that represents money or a percentage), it is usually best to let the library choose the notation.

We can force a stream to use scientific, fixed, or hexadecimal notation by using the appropriate manipulator. The scientific manipulator changes the stream to use scientific notation. The fixed manipulator changes the stream to use fixed decimal.

Under the new library, we can also force floating-point values to use hexadecimal

format by using hexfloat. The new library provides another manipulator, named defaultfloat. This manipulator returns the stream to its default state in which it chooses a notation based on the value being printed.

These manipulators also change the default meaning of the precision for the stream. After executing scientific, fixed, or hexfloat, the precision value controls the number of digits after the decimal point. By default, precision specifies the total number of digits—both before and after the decimal point. Using fixed or scientific lets us print numbers lined up in columns, with the decimal point in a fixed position relative to the fractional part being printed:

Click here to view code image

produces the following output:

default format: 141.421 scientific: 1.414214e+002 fixed decimal: 141.421356 hexadecimal: 0x1.1ad7bcp+7

use defaults: 141.421

By default, the hexadecimal digits and the e used in scientific notation are printed in lowercase. We can use the uppercase manipulator to show those values in uppercase.

Printing the Decimal Point

By default, when the fractional part of a floating-point value is 0, the decimal point is not displayed. The showpoint manipulator forces the decimal point to be printed:

Click here to view code image

The noshowpoint manipulator reinstates the default behavior. The next output expression will have the default behavior, which is to suppress the decimal point if the floating-point value has a 0 fractional part.

Padding the Output

When we print data in columns, we often need fairly fine control over how the data are formatted. The library provides several manipulators to help us accomplish the control we might need:

- setw to specify the minimum space for the next numeric or string value.
- left to left-justify the output.
- right to right-justify the output. Output is right-justified by default.
- internal controls placement of the sign on negative values. internal left-justifies the sign and right-justifies the value, padding any intervening space with blanks.
- setfill lets us specify an alternative character to use to pad the output. By default, the value is a space.

Note

setw, like end1, does not change the internal state of the output stream. It determines the size of only the *next* output.

The following program illustrates these manipulators:

```
int i = -16;
double d = 3.14159;
// pad the first column to use a minimum of 12 positions in the output
cout << "i: " << setw(12) << i << "next col" << '\n'</pre>
      << "d: " << setw(12) << d << "next col" << '\n';
// pad the first column and left-justify all columns
cout << left
      << "i: " << setw(12) << i << "next col" << '\n'
      << "d: " << setw(12) << d << "next col" << '\n'
                                    // restore normal justification
      << right;
// pad the first column and right-justify all columns
cout << right
      << "i: " << setw(12) << i << "next col" << '\n'
      << "d: " << setw(12) << d << "next col" << '\n';
// pad the first column but put the padding internal to the field
cout << internal</pre>
      << "i: " << setw(12) << i << "next col" << '\n'
      << "d: " << setw(12) << d << "next col" << '\n';
// pad the first column, using # as the pad character
cout << setfill('#')</pre>
```

```
<< "i: " << setw(12) << i << "next col" << '\n'
<< "d: " << setw(12) << d << "next col" << '\n'
<< setfill(' ');  // restore the normal pad character</pre>
```

When executed, this program generates

i: -16next col d: 3.14159next col i: -16 next col d: 3.14159 next col i: -16next col d: 3.14159next col i: -16next col 3.14159next col d: i: -######16next col d: #####3.14159next col

Table 17.18. Manipulators Defined in iomanip

```
setfill(ch) Fill whitespace with ch
setprecision(n) Set floating-point precision to n
setw(w) Read or write value to w characters
setbase(b) Output integers in base b
```

Controlling Input Formatting

By default, the input operators ignore whitespace (blank, tab, newline, formfeed, and carriage return). The following loop

```
char ch;
while (cin >> ch)
     cout << ch;</pre>
```

given the input sequence

ab c

executes four times to read the characters a through d, skipping the intervening blanks, possible tabs, and newline characters. The output from this program is

abcd

The noskipws manipulator causes the input operator to read, rather than skip, whitespace. To return to the default behavior, we apply the skipws manipulator:

```
cin >> noskipws; // set cin so that it reads whitespace
while (cin >> ch)
```

```
cout << ch;
cin >> skipws;  // reset cin to the default state so that it discards whitespace
```

Given the same input as before, this loop makes seven iterations, reading whitespace as well as the characters in the input. This loop generates

```
ab c
```

Exercises Section 17.5.1

Exercise 17.34: Write a program that illustrates the use of each manipulator in Tables 17.17 (p. 757) and 17.18.

Exercise 17.35: Write a version of the program from page 758, that printed the square root of 2 but this time print hexadecimal digits in uppercase.

Exercise 17.36: Modify the program from the previous exercise to print the various floating-point values so that they line up in a column.

17.5.2. Unformatted Input/Output Operations

So far, our programs have used only **formatted IO** operations. The input and output operators (<< and >>) format the data they read or write according to the type being handled. The input operators ignore whitespace; the output operators apply padding, precision, and so on.

The library also provides a set of low-level operations that support **unformatted**10. These operations let us deal with a stream as a sequence of uninterpreted bytes.

Single-Byte Operations

Several of the unformatted operations deal with a stream one byte at a time. These operations, which are described in Table 17.19, read rather than ignore whitespace. For example, we can use the unformatted IO operations get and put to read and write the characters one at a time:

This program preserves the whitespace in the input. Its output is identical to the input. It executes the same way as the previous program that used noskipws.

Table 17.19. Single-Byte Low-Level IO Operations

is.get(ch)	Put the next byte from the istream is in character ch. Returns is.
os.put(ch)	Put the character ch onto the ostream os. Returns os.
is.get()	Returns next byte from is as an int.
is.putback(ch)	Put the character ch back on is; returns is.
is.unget()	Move is back one byte; returns is.
is.peek()	Return the next byte as an int but doesn't remove it.

Putting Back onto an Input Stream

Sometimes we need to read a character in order to know that we aren't ready for it. In such cases, we'd like to put the character back onto the stream. The library gives us three ways to do so, each of which has subtle differences from the others:

- peek returns a copy of the next character on the input stream but does not change the stream. The value returned by peek stays on the stream.
- unget backs up the input stream so that whatever value was last returned is still on the stream. We can call unget even if we do not know what value was last taken from the stream.
- putback is a more specialized version of unget: It returns the last value read from the stream but takes an argument that must be the same as the one that was last read.

In general, we are guaranteed to be able to put back at most one value before the next read. That is, we are not guaranteed to be able to call putback or unget successively without an intervening read operation.

int Return Values from Input Operations

The peek function and the version of get that takes no argument return a character from the input stream as an int. This fact can be surprising; it might seem more natural to have these functions return a char.

The reason that these functions return an int is to allow them to return an end-of-file marker. A given character set is allowed to use every value in the char range to represent an actual character. Thus, there is no extra value in that range to use to represent end-of-file.

The functions that return int convert the character they return to unsigned char and then promote that value to int. As a result, even if the character set has characters that map to negative values, the int returned from these operations will be a positive value (§ 2.1.2, p. 35). The library uses a negative value to represent end-of-file, which is thus guaranteed to be distinct from any legitimate character value. Rather than requiring us to know the actual value returned, the iostream header defines a const named EOF that we can use to test if the value returned

from get is end-of-file. It is essential that we use an int to hold the return from these functions:

Click here to view code image

This program operates identically to the one on page 761, the only difference being the version of get that is used to read the input.

Multi-Byte Operations

Some unformatted IO operations deal with chunks of data at a time. These operations can be important if speed is an issue, but like other low-level operations, they are error-prone. In particular, these operations require us to allocate and manage the character arrays (§ 12.2, p. 476) used to store and retrieve data. The multi-byte operations are listed in Table 17.20.

Table 17.20. Multi-Byte Low-Level IO Operations

```
is.get(sink, size, delim)
      Reads up to size bytes from is and stores them in the character array beginning at
      the address pointed to by sink. Reads until encountering the delimcharacter or until
      it has read size bytes or encounters end-of-file. If delim is present, it is left on the
      input stream and not read into sink.
is.getline(sink, size, delim)
      Same behavior as the three-argument version of get but reads and discards delim.
is.read(sink, size)
      Reads up to size bytes into the character array sink. Returns is.
is.gcount()
      Returns number of bytes read from the stream is by the last call to an unformatted
      read operation.
os.write(source, size)
      Writes size bytes from the character array source to os. Returns os.
is.ignore(size, delim)
      Reads and ignores at most size characters up to and including delim. Unlike the
      other unformatted functions, ignore has default arguments: size defaults to 1 and
      delim to end-of-file.
```

The get and getline functions take the same parameters, and their actions are similar but not identical. In each case, sink is a char array into which the data are placed. The functions read until one of the following conditions occurs:

- size 1 characters are read
- End-of-file is encountered

The delimiter character is encountered

The difference between these functions is the treatment of the delimiter: get leaves the delimiter as the next character of the istream, whereas getline reads and discards the delimiter. In either case, the delimiter is not stored in sink.

Warning

It is a common error to intend to remove the delimiter from the stream but to forget to do so.

Determining How Many Characters Were Read

Several of the read operations read an unknown number of bytes from the input. We can call grount to determine how many characters the last unformatted input operation read. It is essential to call grount before any intervening unformatted input operation. In particular, the single-character operations that put characters back on the stream are also unformatted input operations. If peek, unget, or putback are called before calling gount, then the return value will be 0.

17.5.3. Random Access to a Stream

The various stream types generally support random access to the data in their associated stream. We can reposition the stream so that it skips around, reading first the last line, then the first, and so on. The library provides a pair of functions to seek to a given location and to tell the current location in the associated stream.

Note

Random IO is an inherently system-dependent. To understand how to use these features, you must consult your system's documentation.

Although these seek and tell functions are defined for all the stream types, whether they do anything useful depends on the device to which the stream is bound. On most systems, the streams bound to cin, cout, cerr, and clog do not support random access—after all, what would it mean to jump back ten places when we're writing directly to cout? We can call the seek and tell functions, but these functions will fail at run time, leaving the stream in an invalid state.

Caution: Low-Level Routines Are Error-Prone

In general, we advocate using the higher-level abstractions provided by the

library. The IO operations that return int are a good example of why.

It is a common programming error to assign the return, from get or peek to a char rather than an int. Doing so is an error, but an error the compiler will not detect. Instead, what happens depends on the machine and on the input data. For example, on a machine in which chars are implemented as unsigned chars, this loop will run forever:

Click here to view code image

The problem is that when get returns EOF, that value will be converted to an unsigned char value. That converted value is no longer equal to the int value of EOF, and the loop will continue forever. Such errors are likely to be caught in testing.

On machines for which chars are implemented as signed chars, we can't say with confidence what the behavior of the loop might be. What happens when an out-of-bounds value is assigned to a signed value is up to the compiler. On many machines, this loop will appear to work, unless a character in the input matches the EOF value. Although such characters are unlikely in ordinary data, presumably low-level IO is necessary only when we read binary values that do not map directly to ordinary characters and numeric values. For example, on our machine, if the input contains a character whose value is '\377', then the loop terminates prematurely. '\377' is the value on our machine to which -1 converts when used as a signed char. If the input has this value, then it will be treated as the (premature) end-of-file indicator.

Such bugs do not happen when we read and write typed values. If you can use the more type-safe, higher-level operations supported by the library, do so.

Exercises Section 17.5.2

Exercise 17.37: Use the unformatted version of getline to read a file a line at a time. Test your program by giving it a file that contains empty lines as well as lines that are longer than the character array that you pass to getline.

Exercise 17.38: Extend your program from the previous exercise to print each word you read onto its own line.

Warning

Because the istream and ostream types usually do not support random access, the remainder of this section should be considered as applicable to only the fstream and sstream types.

Seek and Tell Functions

To support random access, the IO types maintain a marker that determines where the next read or write will happen. They also provide two functions: One repositions the marker by seeking to a given position; the second tells us the current position of the marker. The library actually defines two pairs of seek and tell functions, which are described in Table 17.21. One pair is used by input streams, the other by output streams. The input and output versions are distinguished by a suffix that is either a g or a p. The g versions indicate that we are "getting" (reading) data, and the p functions indicate that we are "putting" (writing) data.

Table 17.21. Seek and Tell Functions

tellg()	Return the current position of the marker in an input stream (tellg
tellp()	or an output stream (tellp).
seekg (pos)	Reposition the marker in an input or output stream to the given abso-
seekp (pos)	lute address in the stream. pos is usually a value returned by a previous call to the corresponding tellg or tellp function.
seekp(off, from)	Reposition the marker for an input or output stream integral number
seekg(off, from)	off characters ahead or behind from, from can be one of
	 beg, seek relative to the beginning of the stream
	 cur, seek relative to the current position of the stream
	 end, seek relative to the end of the stream

Logically enough, we can use only the q versions on an istream and on the types ifstream and istringstream that inherit from istream (§ 8.1, p. 311). We can use only the p versions on an ostream and on the types that inherit from it, ofstream and ostringstream. An iostream, fstream, or stringstream can both read and write the associated stream; we can use either the g or p versions on objects of these types.

There Is Only One Marker

The fact that the library distinguishes between the "putting" and "getting" versions of the seek and tell functions can be misleading. Even though the library makes this distinction, it maintains only a single marker in a stream—there is not a distinct read

marker and write marker.

When we're dealing with an input-only or output-only stream, the distinction isn't even apparent. We can use only the g or only the p versions on such streams. If we attempt to call tellp on an ifstream, the compiler will complain. Similarly, it will not let us call seekg on an ostringstream.

The fstream and stringstream types can read and write the same stream. In these types there is a single buffer that holds data to be read and written and a single marker denoting the current position in the buffer. The library maps both the g and p positions to this single marker.

Note

Because there is only a single marker, we *must* do a seek to reposition the marker whenever we switch between reading and writing.

Repositioning the Marker

There are two versions of the seek functions: One moves to an "absolute" address within the file; the other moves to a byte offset from a given position:

Click here to view code image

```
// set the marker to a fixed position
seekg(new_position);  // set the read marker to the given pos_type location
seekp(new_position);  // set the write marker to the given pos_type location
// offset some distance ahead of or behind the given starting point
seekg(offset, from);  // set the read marker offset distance from from
seekp(offset, from);  // offset has type off_type
```

The possible values for from are listed in Table 17.21 (on the previous page).

The arguments, new_position and offset, have machine-dependent types named pos_type and off_type, respectively. These types are defined in both istream and ostream. pos_type represents a file position and off_type represents an offset from that position. A value of type off_type can be positive or negative; we can seek forward or backward in the file.

Accessing the Marker

The tellg or tellp functions return a pos_type value denoting the current position of the stream. The tell functions are usually used to remember a location so that we can subsequently seek back to it:

Click here to view code image

Reading and Writing to the Same File

Let's look at a programming example. Assume we are given a file to read. We are to write a newline at the end of the file that contains the relative position at which each line begins. For example, given the following file,

```
abcd
efg
hi
j
```

the program should produce the following modified file:

```
abcd
efg
hi
j
5 9 12 14
```

Note that our program need not write the offset for the first line—it always occurs at position 0. Also note that the offset counts must include the invisible newline character that ends each line. Finally, note that the last number in the output is the offset for the line on which our output begins. By including this offset in our output, we can distinguish our output from the file's original contents. We can read the last number in the resulting file and seek to the corresponding offset to get to the beginning of our output.

Our program will read the file a line at a time. For each line, we'll increment a counter, adding the size of the line we just read. That counter is the offset at which the next line starts:

```
fstream::out);
     if (!inOut) {
         cerr << "Unable to open file!" << endl;
         return EXIT_FAILURE; // EXIT_FAILURE see § 6.3.2 (p. 227)
     // inOut is opened in ate mode, so it starts out positioned at the end
      auto end mark = inOut.tellq();// remember original end-of-file
position
     inOut.seekg(0, fstream::beg); // reposition to the start of the file
     size t cnt = 0;
                                        // accumulator for the byte count
     string line;
                                        // hold each line of input
     // while we haven't hit an error and are still reading the original data
     while (inOut && inOut.tellg() != end_mark
              && getline(inOut, line)) { // and can get another line of
input
          cnt += line.size() + 1; // add 1 to account for the
newline
         auto mark = inOut.tellq(); // remember the read position
          inOut.seekp(0, fstream::end); // set the write marker to the
end
         inOut << cnt;
                                             // write the accumulated length
         // print a separator if this is not the last line
         if (mark != end mark) inOut << " ";</pre>
         inOut.seekg(mark);
                                            // restore the read position
     inOut << "\n";
                                            // write a newline at end-of-
file
     return 0;
}
```

Our program opens its fstream using the in, out, and ate modes (§ 8.4, p. 319). The first two modes indicate that we intend to read and write the same file. Specifying ate positions the read and write markers at the end of the file. As usual, we check that the open succeeded, and exit if it did not (§ 6.3.2, p. 227).

Because our program writes to its input file, we can't use end-of-file to signal when it's time to stop reading. Instead, our loop must end when it reaches the point at which the original input ended. As a result, we must first remember the original end-of-file position. Because we opened the file in ate mode, inout is already positioned at the end. We store the current (i.e., the original end) position in end_mark. Having remembered the end position, we reposition the read marker at the beginning of the file by seeking to the position 0 bytes from the beginning of the file.

The while loop has a three-part condition: We first check that the stream is valid; if so, we check whether we've exhausted our original input by comparing the current read position (returned by tellg) with the position we remembered in end_mark.

Finally, assuming that both tests succeeded, we call getline to read the next line of input. If getline succeeds, we perform the body of the loop.

The loop body starts by remembering the current position in mark. We save that position in order to return to it after writing the next relative offset. The call to seekp repositions the write marker to the end of the file. We write the counter value and then seekg back to the position we remembered in mark. Having restored the marker, we're ready to repeat the condition in the while.

Each iteration of the loop writes the offset of the next line. Therefore, the last iteration of the loop takes care of writing the offset of the last line. However, we still need to write a newline at the end of the file. As with the other writes, we call seekp to position the file at the end before writing the newline.

Exercises Section 17.5.3

Exercise 17.39: Write your own version of the seek program presented in this section.

Chapter Summary

This chapter covered additional IO operations and four library types: tuple, bitset, regular expressions, and random numbers.

A tuple is a template that allows us to bundle together members of disparate types into a single object. Each tuple contains a specified number of members, but the library imposes no limit on the number of members we can define for a given tuple type.

A bitset lets us define collections of bits of a specified size. The size of a bitset is not constrained to match any of the integral types, and can even exceed them. In addition to supporting the normal bitwise operators (§ 4.8, p. 152), bitset defines a number of named operations that let us manipulate the state of particular bits in the bitset.

The regular-expression library provides a collection of classes and functions: The regex class manages regular expressions written in one of several common regular-expression languages. The match classes hold information about a specific match. These classes are used by the regex_search and regex_match functions. These functions take a regex object and a character sequence and detect whether the regular expression in that regex matches the given character sequence. The regex iterator types are iterator adaptors that use regex_search to iterate through an input sequence and return each matching subsequence. There is also a regex_replace function that lets us replace the matched part of a given input sequence with a specified alternative.

The random-number library is a collection of random-number engines and distribution classes. A random-number engine returns a sequence of uniformly distributed integral values. The library defines several engines that have different performance characteristics. The default_random_engine is defined as the engine that should be suitable for most casual uses. The library also defines 20 distribution types. These distribution types use an engine to deliver random numbers of a specified type in a given range that are distributed according to a specified probability distribution.

Defined Terms

bitset Standard library class that holds a collection of bits of a size that is known at compile time, and provides operations to test and set the bits in the collection.

cmatch Container of csub_match objects that provides information about the match to a regex on const char* input sequences. The first element in the container describes the overall match results. The subsequent elements describe the results for the subexpressions.

cregex_iterator Like sregex_iterator except that it iterates over an array of char.

csub_match Type that holds the results of a regular expression match to a const char*. Can represent the entire match or a subexpression.

default random engine Type alias for the random number engine intended for normal use.

formatted IO IO operations that use the types of the objects being read or written to define the actions of the operations. Formatted input operations perform whatever transformations are appropriate to the type being read, such as converting ASCII numeric strings to the indicated arithmetic type and (by default) ignoring whitespace. Formatted output routines convert types to printable character representations, pad the output, and may perform other, type-specific transformations.

get Template function that returns the specified member for a given tuple. For example, get<0>(t) returns the first element from the tuple t.

high-order Bits in a bitset with the largest indices.

low-order Bits in a bitset with the lowest indices.

manipulator A function-like object that "manipulates" a stream. Manipulators can be used as the right-hand operand to the overloaded IO operators, << and >>. Most manipulators change the internal state of the object. Such manipulators often come in pairs—one to change the state and the other to return the stream

to its default state.

random-number distribution Standard library type that transforms the output of a random-number engine according to its named distribution. For example, uniform_int_distribution<T> generates uniformly distributed integers of type T, normal_distribution<T> generates normally distributed numbers, and so on.

random-number engine Library type that generates random unsigned numbers. Engines are intended to be used only as inputs to random-number distributions.

random-number generator Combination of a random-number engine type and a distribution type.

regex Class that manages a regular expression.

regex_error Exception type thrown to indicate a syntactic error in a regular expression.

regex_match Function that determines whether the entire input sequence matches the given regex object.

regex_replace Function that uses a regex object to replace matching subexpressions in an input sequence using a given format.

regex_search Function that uses a regex object to find a matching subsequence of a given input sequence.

regular expression A way of describing a sequence of characters.

seed Value supplied to a random-number engine that causes it to move to a new point in the sequence of number that it generates.

smatch Container of ssub_match objects that provides information about the match to a regex on string input sequences. The first element in the container describes the overall match results. The subsequent elements describe the results for the subexpressions.

sregex_iterator Iterator that iterates over a string using a given regex object to find matches in the given string. The constructor positions the iterator on the first match by calling regex_search. Incrementing the iterator calls regex_search starting just after the current match in the given string.
Dereferencing the iterator returns an smatch object describing the current match.

ssub_match Type that holds results of a regular expression match to a string. Can represent the entire match or a subexpression.

subexpression Parenthesized component of a regular expression pattern.

tuple Template that generates types that hold unnamed members of specified types. There is no fixed limit on the number of members a tuple can be defined to have.

unformatted IO Operations that treat the stream as an undifferentiated byte stream. Unformatted operations place more of the burden for managing the IO on the user.

Section 18.3 Multiple and Virtual Inheritance

Chapter Summary

Defined Terms

C++ is used on problems small enough to be solved by a single programmer after a few hours' work and on problems requiring enormous systems consisting of tens of millions of lines of code developed and modified by hundreds of programmers over many years. The facilities that we covered in the earlier parts of this book are equally useful across this range of programming problems.

The language includes some features that are most useful on systems that are more complicated than those that a small team can manage. These features—exception handling, namespaces, and multiple inheritance—are the topic of this chapter.

Large-scale programming places greater demands on programming languages than do the needs of systems that can be developed by small teams of programmers. Among the needs that distinguish large-scale applications are

- The ability to handle errors across independently developed subsystems
- The ability to use libraries developed more or less independently
- The ability to model more complicated application concepts

This chapter looks at three features in C++ that are aimed at these needs: exception handling, namespaces, and multiple inheritance.

18.1. Exception Handling

Exception handling allows independently developed parts of a program to communicate about and handle problems that arise at run time. Exceptions let us separate problem detection from problem resolution. One part of the program can

detect a problem and can pass the job of resolving that problem to another part of the program. The detecting part need not know anything about the handling part, and vice versa.

In § 5.6 (p. 193) we introduced the basic concepts and mechanics of using exceptions. In this section we'll expand our coverage of these basics. Effective use of exception handling requires understanding what happens when an exception is thrown, what happens when it is caught, and the meaning of the objects that communicate what went wrong.

18.1.1. Throwing an Exception

In C++, an exception is **raised** by **throwing** an expression. The type of the thrown expression, together with the current call chain, determines which **handler** will deal with the exception. The selected handler is the one nearest in the call chain that matches the type of the thrown object. The type and contents of that object allow the throwing part of the program to inform the handling part about what went wrong.

When a throw is executed, the statement(s) following the throw are not executed. Instead, control is transferred from the throw to the matching catch. That catch might be local to the same function or might be in a function that directly or indirectly called the function in which the exception occurred. The fact that control passes from one location to another has two important implications:

- Functions along the call chain may be prematurely exited.
- When a handler is entered, objects created along the call chain will have been destroyed.

Because the statements following a throw are not executed, a throw is like a return: It is usually part of a conditional statement or is the last (or only) statement in a function.

Stack Unwinding

When an exception is thrown, execution of the current function is suspended and the search for a matching catch clause begins. If the throw appears inside a **try block**, the catch clauses associated with that try are examined. If a matching catch is found, the exception is handled by that catch. Otherwise, if the try was itself nested inside another try, the search continues through the catch clauses of the enclosing trys. If no matching catch is found, the current function is exited, and the search continues in the calling function.

If the call to the function that threw is in a try block, then the catch clauses associated with that try are examined. If a matching catch is found, the exception is handled. Otherwise, if that try was nested, the catch clauses of the enclosing trys are searched. If no catch is found, the calling function is also exited. The search continues in the function that called the just exited one, and so on.

This process, known as **stack unwinding**, continues up the chain of nested function calls until a catch clause for the exception is found, or the main function itself is exited without having found a matching catch.

Assuming a matching catch is found, that catch is entered, and the program continues by executing the code inside that catch. When the catch completes, execution continues at the point immediately after the last catch clause associated with that try block.

If no matching catch is found, the program is exited. Exceptions are intended for events that prevent the program from continuing normally. Therefore, once an exception is raised, it cannot remain unhandled. If no matching catch is found, the program calls the library terminate function. As its name implies, terminate stops execution of the program.

An exception that is not caught terminates the program.

Objects Are Automatically Destroyed during Stack Unwinding

During stack unwinding, blocks in the call chain may be exited prematurely. In general, these blocks will have created local objects. Ordinarily, local objects are destroyed when the block in which they are created is exited. Stack unwinding is no exception. When a block is exited during stack unwinding, the compiler guarantees that objects created in that block are properly destroyed. If a local object is of class type, the destructor for that object is called automatically. As usual, the compiler does no work to destroy objects of built-in type.

If an exception occurs in a constructor, then the object under construction might be only partially constructed. Some of its members might have been initialized, but others might not have been initialized before the exception occurred. Even if the object is only partially constructed, we are guaranteed that the constructed members will be properly destroyed.

Similarly, an exception might occur during initialization of the elements of an array or a library container type. Again, we are guaranteed that the elements (if any) that were constructed before the exception occurred will be destroyed.

Destructors and Exceptions

The fact that destructors are run—but code inside a function that frees a resource may be bypassed—affects how we structure our programs. As we saw in § 12.1.4 (p. 467), if a block allocates a resource, and an exception occurs before the code that

frees that resource, the code to free the resource will not be executed. On the other hand, resources allocated by an object of class type generally will be freed by their destructor. By using classes to control resource allocation, we ensure that resources are properly freed, whether a function ends normally or via an exception.

The fact that destructors are run during stack unwinding affects how we write destructors. During stack unwinding, an exception has been raised but is not yet handled. If a new exception is thrown during stack unwinding and not caught in the function that threw it, terminate is called. Because destructors may be invoked during stack unwinding, they should never throw exceptions that the destructor itself does not handle. That is, if a destructor does an operation that might throw, it should wrap that operation in a try block and handle it locally to the destructor.

In practice, because destructors free resources, it is unlikely that they will throw exceptions. All of the standard library types guarantee that their destructors will not raise an exception.

Warning

During stack unwinding, destructors are run on local objects of class type. Because destructors are run automatically, they should not throw. If, during stack unwinding, a destructor throws an exception that it does not also catch, the program will be terminated.

The Exception Object

The compiler uses the thrown expression to copy initialize (§ 13.1.1, p. 497) a special object known as the exception object. As a result, the expression in a throw must have a complete type (§ 7.3.3, p. 278). Moreover, if the expression has class type, that class must have an accessible destructor and an accessible copy or move constructor. If the expression has an array or function type, the expression is converted to its corresponding pointer type.

The exception object resides in space, managed by the compiler, that is guaranteed to be accessible to whatever catch is invoked. The exception object is destroyed after the exception is completely handled.

As we've seen, when an exception is thrown, blocks along the call chain are exited until a matching handler is found. When a block is exited, the memory used by the local objects in that block is freed. As a result, it is almost certainly an error to throw a pointer to a local object. It is an error for the same reasons that it is an error to return a pointer to a local object (§ 6.3.2, p. 225) from a function. If the pointer points to an object in a block that is exited before the catch, then that local object will have been destroyed before the catch.

When we throw an expression, the static, compile-time type (§ 15.2.3, p. 601) of

that expression determines the type of the exception object. This point is essential to keep in mind, because many applications throw expressions whose type comes from an inheritance hierarchy. If a throw expression dereferences a pointer to a base-class type, and that pointer points to a derived-type object, then the thrown object is sliced down (§ 15.2.3, p. 603); only the base-class part is thrown.

Warning

Throwing a pointer requires that the object to which the pointer points exist wherever the corresponding handler resides.

Exercises Section 18.1.1

Exercise 18.1: What is the type of the exception object in the following throws?

```
(a) range_error r("error");
throw r;
(b) exception *p = &r;
throw *p;
```

What would happen if the throw in (b) were written as throw p?

Exercise 18.2: Explain what happens if an exception occurs at the indicated point:

Click here to view code image

```
void exercise(int *b, int *e)
    vector<int> v(b, e);
    int *p = new int[v.size()];
    ifstream in("ints");
    // exception occurs here
```

Exercise 18.3: There are two ways to make the previous code work correctly if an exception is thrown. Describe them and implement them.

18.1.2. Catching an Exception

The exception declaration in a catch clause looks like a function parameter list with exactly one parameter. As in a parameter list, we can omit the name of the catch parameter if the catch has no need to access the thrown expression.

The type of the declaration determines what kinds of exceptions the handler can

catch. The type must be a complete type (§ 7.3.3, p. 278). The type can be an Ivalue reference but may not be an rvalue reference (§ 13.6.1, p. 532).

When a catch is entered, the parameter in its exception declaration is initialized by the exception object. As with function parameters, if the catch parameter has a nonreference type, then the parameter in the catch is a copy of the exception object; changes made to the parameter inside the catch are made to a local copy, not to the exception object itself. If the parameter has a reference type, then like any reference parameter, the catch parameter is just another name for the exception object. Changes made to the parameter are made to the exception object.

Also like a function parameter, a catch parameter that has a base-class type can be initialized by an exception object that has a type derived from the parameter type. If the catch parameter has a nonreference type, then the exception object will be sliced down (§ 15.2.3, p. 603), just as it would be if such an object were passed to an ordinary function by value. On the other hand, if the parameter is a reference to a base-class type, then the parameter is bound to the exception object in the usual way.

Again, as with a function parameter, the static type of the exception declaration determines the actions that the catch may perform. If the catch parameter has a base-class type, then the catch cannot use any members that are unique to the derived type.

Best Practices

Ordinarily, a catch that takes an exception of a type related by inheritance ought to define its parameter as a reference.

Finding a Matching Handler

During the search for a matching catch, the catch that is found is not necessarily the one that matches the exception best. Instead, the selected catch is the first one that matches the exception at all. As a consequence, in a list of catch clauses, the most specialized catch must appear first.

Because catch clauses are matched in the order in which they appear, programs that use exceptions from an inheritance hierarchy must order their catch clauses so that handlers for a derived type occur before a catch for its base type.

The rules for when an exception matches a catch exception declaration are much more restrictive than the rules used for matching arguments with parameter types. Most conversions are not allowed—the types of the exception and the catch declaration must match exactly with only a few possible differences:

 Conversions from nonconst to const are allowed. That is, a throw of a nonconst object can match a catch specified to take a reference to const.

- Conversions from derived type to base type are allowed.
- An array is converted to a pointer to the type of the array; a function is converted to the appropriate pointer to function type.

No other conversions are allowed to match a catch. In particular, neither the standard arithmetic conversions nor conversions defined for class types are permitted.

Note

Multiple catch clauses with types related by inheritance must be ordered from most derived type to least derived.

Rethrow

Sometimes a single catch cannot completely handle an exception. After some corrective actions, a catch may decide that the exception must be handled by a function further up the call chain. A catch passes its exception out to another catch by rethrowing the exception. A rethrow is a throw that is not followed by an expression:

```
throw;
```

An empty throw can appear only in a catch or in a function called (directly or indirectly) from a catch. If an empty throw is encountered when a handler is not active, terminate is called.

A rethrow does not specify an expression; the (current) exception object is passed up the chain.

In general, a catch might change the contents of its parameter. If, after changing its parameter, the catch rethrows the exception, then those changes will be propagated only if the catch's exception declaration is a reference:

Click here to view code image

The Catch-All Handler

Sometimes we want to catch any exception that might occur, regardless of type. Catching every possible exception can be a problem: Sometimes we don't know what types might be thrown. Even when we do know all the types, it may be tedious to provide a specific catch clause for every possible exception. To catch all exceptions, we use an ellipsis for the exception declaration. Such handlers, sometimes known as catch-all handlers, have the form catch(...). A catch-all clause matches any type of exception.

A catch(...) is often used in combination with a rethrow expression. The catch does whatever local work can be done and then rethrows the exception:

Click here to view code image

```
void manip() {
    try {
        // actions that cause an exception to be thrown
    }
    catch (...) {
        // work to partially handle the exception
        throw;
    }
}
```

A catch(...) clause can be used by itself or as one of several catch clauses.

Note

If a catch(...) is used in combination with other catch clauses, it must be last. Any catch that follows a catch-all can never be matched.

18.1.3. Function try Blocks and Constructors

In general, exceptions can occur at any point in the program's execution. In particular, an exception might occur while processing a constructor initializer. Constructor initializers execute before the constructor body is entered. A catch inside the constructor body can't handle an exception thrown by a constructor initializer because a try block inside the constructor body would not yet be in effect when the exception is thrown.

Exercises Section 18.1.2

Exercise 18.4: Looking ahead to the inheritance hierarchy in Figure 18.1 (p. 783), explain what's wrong with the following try block. Correct it.

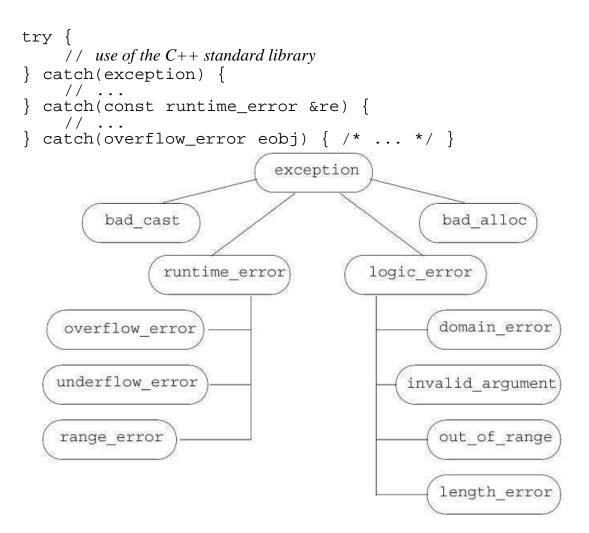

Figure 18.1. Standard exception Class Hierarchy

Exercise 18.5: Modify the following main function to catch any of the exception types shown in Figure 18.1 (p. 783):

Click here to view code image

```
int main() {
    // use of the C++ standard library
}
```

The handlers should print the error message associated with the exception before calling abort (defined in the header cstdlib) to terminate main.

Exercise 18.6: Given the following exception types and catch clauses, write a throw expression that creates an exception object that can be caught by each catch clause:

```
(a) class exceptionType { };
catch(exceptionType *pet) { }
(b) catch(...) { }
(c) typedef int EXCPTYPE;
```

```
catch(EXCPTYPE) { }
```

To handle an exception from a constructor initializer, we must write the constructor as a **function try block**. A function try block lets us associate a group of catch clauses with the initialization phase of a constructor (or the destruction phase of a destructor) as well as with the constructor's (or destructor's) function body. As an example, we might wrap the Blob constructors (§ 16.1.2, p. 662) in a function try block:

Click here to view code image

Notice that the keyword try appears before the colon that begins the constructor initializer list and before the curly brace that forms the (in this case empty) constructor function body. The catch associated with this try can be used to handle exceptions thrown either from within the member initialization list or from within the constructor body.

It is worth noting that an exception can happen while initializing the constructor's parameters. Such exceptions are *not* part of the function try block. The function try block handles only exceptions that occur once the constructor begins executing. As with any other function call, if an exception occurs during parameter initialization, that exception is part of the calling expression and is handled in the caller's context.

Note

The only way for a constructor to handle an exception from a constructor initializer is to write the constructor as a function try block.

Exercises Section 18.1.3

Exercise 18.7: Define your Blob and BlobPtr classes from Chapter 16 to use function try blocks for their constructors.

18.1.4. The noexcept Exception Specification

It can be helpful both to users and to the compiler to know that a function will not

throw any exceptions. Knowing that a function will not throw simplifies the task of writing code that calls that function. Moreover, if the compiler knows that no exceptions will be thrown, it can (sometimes) perform optimizations that must be suppressed if code might throw.

C++

Under the new standard, a function can specify that it does not throw exceptions by providing a **noexcept specification**. The keyword noexcept following the function parameter list indicates that the function won't throw:

Click here to view code image

```
void recoup(int) noexcept;  // won't throw
void alloc(int);  // might throw
```

These declarations say that recoup will not throw any exceptions and that alloc might. We say that recoup has a **nonthrowing specification**.

The noexcept specifier must appear on all of the declarations and the corresponding definition of a function or on none of them. The specifier precedes a trailing return (§ 6.3.3, p. 229). We may also specify noexcept on the declaration and definition of a function pointer. It may not appear in a typedef or type alias. In a member function the noexcept specifier follows any const or reference qualifiers, and it precedes final, override, or = 0 on a virtual function.

Violating the Exception Specification

It is important to understand that the compiler does not check the noexcept specification at compile time. In fact, the compiler is not permitted to reject a function with a noexcept specifier merely because it contains a throw or calls a function that might throw (however, kind compilers will warn about such usages):

Click here to view code image

As a result, it is possible that a function that claims it will not throw will in fact throw. If a noexcept function does throw, terminate is called, thereby enforcing the promise not to throw at run time. It is unspecified whether the stack is unwound. As a result, noexcept should be used in two cases: if we are confident that the function won't throw, and/or if we don't know what we'd do to handle the error anyway.

Specifying that a function won't throw effectively promises the *callers* of the nonthrowing function that they will never need to deal with exceptions. Either the

function won't throw, or the whole program will terminate; the caller escapes responsibility either way.

Warning

The compiler in general cannot, and does not, verify exception specifications at compile time.

Backward Compatibility: Exception Specifications

Earlier versions of C++ had a more elaborate scheme of exception specifications that allowed us to specify the types of exceptions that a function might throw. A function can specify the keyword throw followed by a parenthesized list of types that the function might throw. The throw specifier appeared in the same place as the noexcept specifier does in the current language.

This approach was never widely used and has been deprecated in the current standard. Although these more elaborate specifiers have been deprecated, there is one use of the old scheme that is in widespread use. A function that is designated by throw() promises not to throw any exceptions:

Click here to view code image

```
void recoup(int) noexcept; // recoup doesn't throw
void recoup(int) throw(); // equivalent declaration
```

These declarations of recoup are equivalent. Both say that recoup won't throw.

Arguments to the noexcept Specification

The noexcept specifier takes an optional argument that must be convertible to bool: If the argument is true, then the function won't throw; if the argument is false, then the function might throw:

Click here to view code image

```
void recoup(int) noexcept(true); // recoup won't throw
void alloc(int) noexcept(false); // alloc can throw
```

The noexcept Operator

Arguments to the noexcept specifier are often composed using the **noexcept operator**. The noexcept operator is a unary operator that returns a bool rvalue constant expression that indicates whether a given expression might throw. Like sizeof (§ 4.9, p. 156), noexcept does not evaluate its operand.

For example, this expression yields true:

Click here to view code image

```
noexcept(recoup(i)) // true if calling recoup can't throw, false
otherwise
```

because we declared recoup with a noexcept specifier. More generally,

```
noexcept(e)
```

is true if all the functions called by e have nonthrowing specifications and e itself does not contain a throw. Otherwise, noexcept(e) returns false.

We can use the noexcept operator to form an exception specifier as follows:

Click here to view code image

```
void f() noexcept(noexcept(g())); // f has same exception specifier as g
```

If the function g promises not to throw, then f also is nonthrowing. If g has no exception specifier, or has an exception specifier that allows exceptions, then f also might throw.

Note

noexcept has two meanings: It is an exception specifier when it follows a function's parameter list, and it is an operator that is often used as the bool argument to a noexcept exception specifier.

Exception Specifications and Pointers, Virtuals, and Copy Control

Although the noexcept specifier is not part of a function's type, whether a function has an exception specification affects the use of that function.

A pointer to function and the function to which that pointer points must have compatible specifications. That is, if we declare a pointer that has a nonthrowing exception specification, we can use that pointer only to point to similarly qualified functions. A pointer that specifies (explicitly or implicitly) that it might throw can point to any function, even if that function includes a promise not to throw:

```
// both recoup and pfl promise not to throw
void (*pf1)(int) noexcept = recoup;

// ok: recoup won't throw; it doesn't matter that pf2 might
void (*pf2)(int) = recoup;

pf1 = alloc; // error: alloc might throw but pfl said it wouldn't
pf2 = alloc; // ok: both pf2 and alloc might throw
```

If a virtual function includes a promise not to throw, the inherited virtuals must also promise not to throw. On the other hand, if the base allows exceptions, it is okay for the derived functions to be more restrictive and promise not to throw:

Click here to view code image

```
class Base {
public:
    virtual double f1(double) noexcept; // doesn't throw
    virtual int f2() noexcept(false); // can throw
    virtual void f3(); // can throw
};

class Derived: public Base {
public:
    double f1(double); // error: Base::f1 promises not to throw
    int f2() noexcept(false); // ok: same specification as Base::f2
    void f3() noexcept; // ok: Derived f3 is more restrictive
};
```

When the compiler synthesizes the copy-control members, it generates an exception specification for the synthesized member. If all the corresponding operation for all the members and base classes promise not to throw, then the synthesized member is noexcept. If any function invoked by the synthesized member can throw, then the synthesized member is noexcept(false). Moreover, if we do not provide an exception specification for a destructor that we do define, the compiler synthesizes one for us. The compiler generates the same specification as it would have generated had it synthesized the destructor for that class.

Exercises Section 18.1.4

Exercise 18.8: Review the classes you've written and add appropriate exception specifications to their constructors and destructors. If you think one of your destructors might throw, change the code so that it cannot throw.

18.1.5. Exception Class Hierarchies

The standard-library exception classes (§ 5.6.3, p. 197) form the inheritance hierarchy (Chapter 15) as shown in Figure 18.1.

The only operations that the exception types define are the copy constructor, copy-assignment operator, a virtual destructor, and a virtual member named what. The what function returns a const char* that points to a null-terminated character array, and is guaranteed not to throw any exceptions.

The exception, bad_cast, and bad_alloc classes also define a default constructor. The runtime_error and logic_error classes do not have a default constructor but do have constructors that take a C-style character string or a library string argument. Those arguments are intended to give additional information about the error. In these classes, what returns the message used to initialize the exception object. Because what is virtual, if we catch a reference to the base-type, a call to the what function will execute the version appropriate to the dynamic type of the exception object.

Exception Classes for a Bookstore Application

Applications often extend the exception hierarchy by defining classes derived from exception (or from one of the library classes derived from exception). These application-specific classes represent exceptional conditions specific to the application domain.

If we were building a real bookstore application, our classes would have been much more complicated than the ones presented in this Primer. One such complexity would be how these classes handled exceptions. In fact, we probably would have defined our own hierarchy of exceptions to represent application-specific problems. Our design might include classes such as

Click here to view code image

Our application-specific exception types inherit them from the standard exception classes. As with any hierarchy, we can think of the exception classes as being

organized into layers. As the hierarchy becomes deeper, each layer becomes a more specific exception. For example, the first and most general layer of the hierarchy is represented by class exception. All we know when we catch an object of type exception is that something has gone wrong.

The second layer specializes <code>exception</code> into two broad categories: run-time or logic errors. Run-time errors represent things that can be detected only when the program is executing. Logic errors are, in principle, errors that we could have detected in our application.

Our bookstore exception classes further refine these categories. The class named out_of_stock represents something, particular to our application, that can go wrong at run time. It would be used to signal that an order cannot be fulfilled. The class isbn_mismatch represents a more particular form of logic_error. In principle, a program could prevent and handle this error by comparing the results of isbn() on the objects.

Using Our Own Exception Types

We use our own exception classes in the same way that we use one of the standard library classes. One part of the program throws an object of one of these types, and another part catches and handles the indicated problem. As an example, we might define the compound addition operator for our Sales_data class to throw an error of type isbn_mismatch if it detected that the ISBNS didn't match:

Click here to view code image

Code that uses the compound addition operator (or ordinary addition operator, which itself uses the compound addition operator) can detect this error, write an appropriate error message, and continue:

```
// use the hypothetical bookstore exceptions
Sales_data item1, item2, sum;
while (cin >> item1 >> item2) { // read two transactions
    try {
        sum = item1 + item2; // calculate their sum
```

Exercises Section 18.1.5

Exercise 18.9: Define the bookstore exception classes described in this section and rewrite your Sales_data compound assignment operator to throw an exception.

Exercise 18.10: Write a program that uses the Sales_data addition operator on objects that have differing ISBNS. Write two versions of the program: one that handles the exception and one that does not. Compare the behavior of the programs so that you become familiar with what happens when an uncaught exception occurs.

Exercise 18.11: Why is it important that the what function doesn't throw?

18.2. Namespaces

Large programs tend to use independently developed libraries. Such libraries also tend to define a large number of global names, such as classes, functions, and templates. When an application uses libraries from many different vendors, it is almost inevitable that some of these names will clash. Libraries that put names into the global namespace are said to cause **namespace pollution**.

Traditionally, programmers avoided namespace pollution by using very long names for the global entities they defined. Those names often contained a prefix indicating which library defined the name:

Click here to view code image

```
class cplusplus_primer_Query { ... };
string cplusplus_primer_make_plural(size_t, string&);
```

This solution is far from ideal: It can be cumbersome for programmers to write and read programs that use such long names.

Namespaces provide a much more controlled mechanism for preventing name collisions. Namespaces partition the global namespace. A namespace is a scope. By defining a library's names inside a namespace, library authors (and users) can avoid the limitations inherent in global names.

18.2.1. Namespace Definitions

A namespace definition begins with the keyword namespace followed by the namespace name. Following the namespace name is a sequence of declarations and definitions delimited by curly braces. Any declaration that can appear at global scope can be put into a namespace: classes, variables (with their initializations), functions (with their definitions), templates, and other namespaces:

Click here to view code image

This code defines a namespace named cplusplus_primer with four members: three classes and an overloaded + operator.

As with any name, a namespace name must be unique within the scope in which the namespace is defined. Namespaces may be defined at global scope or inside another namespace. They may not be defined inside a function or a class.

Note

A namespace scope does not end with a semicolon.

Each Namespace Is a Scope

As is the case for any scope, each name in a namespace must refer to a unique entity within that namespace. Because different namespaces introduce different scopes, different namespaces may have members with the same name.

Names defined in a namespace may be accessed directly by other members of the namespace, including scopes nested within those members. Code outside the namespace must indicate the namespace in which the name is defined:

Click here to view code image

If another namespace (say, AddisonWesley) also provides a Query class and we want to use that class instead of the one defined in cplusplus_primer, we can do so by modifying our code as follows:

```
AddisonWesley::Query q = AddisonWesley::Query("hello");
```

Namespaces Can Be Discontiguous

As we saw in § 16.5 (p. 709), unlike other scopes, a namespace can be defined in several parts. Writing a namespace definition:

```
namespace nsp {
// declarations
```

either defines a new namespace named nsp or adds to an existing one. If the name nsp does not refer to a previously defined namespace, then a new namespace with that name is created. Otherwise, this definition opens an existing namespace and adds declarations to that already existing namespace.

The fact that namespace definitions can be discontiguous lets us compose a namespace from separate interface and implementation files. Thus, a namespace can be organized in the same way that we manage our own class and function definitions:

- Namespace members that define classes, and declarations for the functions and objects that are part of the class interface, can be put into header files. These headers can be included by files that use those namespace members.
- The definitions of namespace members can be put in separate source files.

Organizing our namespaces this way also satisfies the requirement that various entities —non-inline functions, static data members, variables, and so forth—may be defined only once in a program. This requirement applies equally to names defined in a namespace. By separating the interface and implementation, we can ensure that the functions and other names we need are defined only once, but the same declaration will be seen whenever the entity is used.

Best Practices

Namespaces that define multiple, unrelated types should use separate files to represent each type (or each collection of related types) that the namespace defines.

Defining the Primer Namespace

Using this strategy for separating interface and implementation, we might define the cplusplus_primer library in several separate files. The declarations for Sales data and its related functions would be placed in Sales data.h, those for the Query classes of Chapter 15 in Query.h, and so on. The corresponding implementation files would be in files such as Sales_data.cc and Query.cc:

Click here to view code image

A program using our library would include whichever headers it needed. The names in those headers are defined inside the cplusplus_primer namespace:

Click here to view code image

```
// ---- user.cc----
// names in the Sales_data.h header are in the cplusplus_primer namespace
#include "Sales_data.h"

int main()
{
    using cplusplus_primer::Sales_data;
    Sales_data trans1, trans2;
    // ...
    return 0;
}
```

This program organization gives the developers and the users of our library the needed modularity. Each class is still organized into its own interface and implementation files. A user of one class need not compile names related to the others. We can hide the implementations from our users, while allowing the files <code>Sales_data.cc</code> and <code>user.cc</code> to be compiled and linked into one program without causing any compile-time or link-time errors. Developers of the library can work independently on the implementation of each type.

It is worth noting that ordinarily, we do not put a #include inside the namespace. If we did, we would be attempting to define all the names in that header as members of the enclosing namespace. For example, if our Sales_data.h file opened the cplusplus_primer before including the string header our program would be in error. It would be attempting to define the std namespace nested inside cplusplus_primer.

Defining Namespace Members

Assuming the appropriate declarations are in scope, code inside a namespace may use the short form for names defined in the same (or in an enclosing) namespace:

Click here to view code image

```
#include "Sales_data.h"
namespace cplusplus_primer { // reopen cplusplus_primer
// members defined inside the namespace may use unqualified names
std::istream&
operator>>(std::istream& in, Sales_data& s) { /* ... */}
}
```

It is also possible to define a namespace member outside its namespace definition. The namespace declaration of the name must be in scope, and the definition must specify the namespace to which the name belongs:

Click here to view code image

As with class members defined outside a class, once the fully qualified name is seen, we are in the scope of the namespace. Inside the <code>cplusplus_primer</code> namespace, we can use other namespace member names without qualification. Thus, even though <code>Sales_data</code> is a member of the <code>cplusplus_primer</code> namespace, we can use its unqualified name to define the parameters in this function.

Although a namespace member can be defined outside its namespace, such definitions must appear in an enclosing namespace. That is, we can define the Sales_data operator+ inside the cplusplus_primer namespace or at global scope. We cannot define this operator in an unrelated namespace.

Template Specializations

Template specializations must be defined in the same namespace that contains the original template (§ 16.5, p. 709). As with any other namespace name, so long as we have declared the specialization inside the namespace, we can define it outside the namespace:

Click here to view code image

// we must declare the specialization as a member of std

The Global Namespace

Names defined at global scope (i.e., names declared outside any class, function, or namespace) are defined inside the **global namespace**. The global namespace is implicitly declared and exists in every program. Each file that defines entities at global scope (implicitly) adds those names to the global namespace.

The scope operator can be used to refer to members of the global namespace. Because the global namespace is implicit, it does not have a name; the notation

```
::member_name
```

refers to a member of the global namespace.

Nested Namespaces

A nested namespace is a namespace defined inside another namespace:

Click here to view code image

```
namespace cplusplus_primer {
    // first nested namespace: defines the Query portion of the library
    namespace QueryLib {
        class Query { /* ... */ };
        Query operator&(const Query&, const Query&);
        // ...
}

// second nested namespace: defines the Sales_data portion of the library
namespace Bookstore {
        class Quote { /* ... */ };
        class Disc_quote : public Quote { /* ... */ };
        // ...
}
```

The cplusplus_primer namespace now contains two nested namespaces: the namespaces named QueryLib and Bookstore.

A nested namespace is a nested scope—its scope is nested within the namespace that contains it. Nested namespace names follow the normal rules: Names declared in an inner namespace hide declarations of the same name in an outer namespace. Names defined inside a nested namespace are local to that inner namespace. Code in the outer parts of the enclosing namespace may refer to a name in a nested namespace only through its qualified name: For example, the name of the class declared in the nested namespace QueryLib is

Click here to view code image

```
cplusplus_primer::QueryLib::Query
```

Inline Namespaces

The new standard introduced a new kind of nested namespace, an **inline namespace**. Unlike ordinary nested namespaces, names in an inline namespace can be used as if they were direct members of the enclosing namespace. That is, we need not qualify names from an inline namespace by their namespace name. We can access them using only the name of the enclosing namespace.

An inline namespace is defined by preceding the keyword namespace with the keyword inline:

Click here to view code image

```
inline namespace FifthEd {
    // namespace for the code from the Primer Fifth Edition
}
namespace FifthEd { // implicitly inline
    class Query_base { /* ... * /};
    // other Query-related declarations
}
```

The keyword must appear on the first definition of the namespace. If the namespace is later reopened, the keyword inline need not be, but may be, repeated.

Inline namespaces are often used when code changes from one release of an application to the next. For example, we can put all the code from the current edition of the Primer into an inline namespace. Code for previous versions would be in non-inlined namespaces:

```
namespace FourthEd {
    class Item_base { /* ... */};
    class Query_base { /* ... */};
    // other code from the Fourth Edition
}
```

The overall cplusplus_primer namespace would include the definitions of both namespaces. For example, assuming that each namespace was defined in a header with the corresponding name, we'd define cplusplus_primer as follows:

Click here to view code image

```
namespace cplusplus_primer {
#include "FifthEd.h"
#include "FourthEd.h"
}
```

Because FifthEd is inline, code that refers to cplusplus_primer:: will get the version from that namespace. If we want the earlier edition code, we can access it as we would any other nested namespace, by using the names of all the enclosing namespaces: for example, cplusplus_primer::FourthEd::Query_base.

Unnamed Namespaces

An unnamed namespace is the keyword namespace followed immediately by a block of declarations delimited by curly braces. Variables defined in an unnamed namespace have static lifetime: They are created before their first use and destroyed when the program ends.

An unnamed namespace may be discontiguous within a given file but does not span files. Each file has its own unnamed namespace. If two files contain unnamed namespaces, those namespaces are unrelated. Both unnamed namespaces can define the same name; those definitions would refer to different entities. If a header defines an unnamed namespace, the names in that namespace define different entities local to each file that includes the header.

Note

Unlike other namespaces, an unnamed namespace is local to a particular file and never spans multiple files.

Names defined in an unnamed namespace are used directly; after all, there is no namespace name with which to qualify them. It is not possible to use the scope operator to refer to members of unnamed namespaces.

Names defined in an unnamed namespace are in the same scope as the scope at which the namespace is defined. If an unnamed namespace is defined at the outermost scope in the file, then names in the unnamed namespace must differ from names defined at global scope:

```
int i; // global declaration for i
```

```
namespace {
     int i;
// ambiguous: defined globally and in an unnested, unnamed namespace
```

In all other ways, the members of an unnamed namespace are normal program entities. An unnamed namespace, like any other namespace, may be nested inside another namespace. If the unnamed namespace is nested, then names in it are accessed in the normal way, using the enclosing namespace name(s):

Click here to view code image

```
namespace local {
     namespace {
          int i;
// ok: i defined in a nested unnamed namespace is distinct from global i
local::i = 42i
```

Unnamed Namespaces Replace File Statics

Prior to the introduction of namespaces, programs declared names as static to make them local to a file. The use of *file statics* is inherited from C. In C, a global entity declared static is invisible outside the file in which it is declared.

Warning

The use of file static declarations is deprecated by the C++ standard. File statics should be avoided and unnamed namespaces used instead.

Exercises Section 18.2.1

Exercise 18.12: Organize the programs you have written to answer the questions in each chapter into their own namespaces. That is, namespace chapter15 would contain code for the Query programs and chapter10 would contain the TextQuery code. Using this structure, compile the Query code examples.

Exercise 18.13: When might you use an unnamed namespace?

Exercise 18.14: Suppose we have the following declaration of the is member of the operator* that a nested namespace mathLib::MatrixLib:

How would you declare this operator in global scope?

18.2.2. Using Namespace Members

Referring to namespace members as namespace_name::member_name is admittedly cumbersome, especially if the namespace name is long. Fortunately, there are ways to make it easier to use namespace members. Our programs have used one of these ways, using declarations (§ 3.1, p. 82). The others, namespace aliases and using directives, will be described in this section.

Namespace Aliases

A **namespace alias** can be used to associate a shorter synonym with a namespace name. For example, a long namespace name such as

Click here to view code image

```
namespace cplusplus_primer { /* ... */ };
can be associated with a shorter synonym as follows:
  namespace primer = cplusplus_primer;
```

A namespace alias declaration begins with the keyword namespace, followed by the alias name, followed by the = sign, followed by the original namespace name and a semicolon. It is an error if the original namespace name has not already been defined as a namespace.

A namespace alias can also refer to a nested namespace:

Click here to view code image

```
namespace Qlib = cplusplus_primer::QueryLib;
Qlib::Query q;
```

Note

A namespace can have many synonyms, or aliases. All the aliases and the original namespace name can be used interchangeably.

using Declarations: A Recap

A using declaration introduces only one namespace member at a time. It allows us to be very specific regarding which names are used in our programs.

Names introduced in a using declaration obey normal scope rules: They are visible from the point of the using declaration to the end of the scope in which the declaration appears. Entities with the same name defined in an outer scope are hidden. The unqualified name may be used only within the scope in which it is declared and in scopes nested within that scope. Once the scope ends, the fully qualified name must be used.

A using declaration can appear in global, local, namespace, or class scope. In class scope, such declarations may only refer to a base class member (§ 15.5, p. 615).

using Directives

A using directive, like a using declaration, allows us to use the unqualified form of a namespace name. Unlike a using declaration, we retain no control over which names are made visible—they all are.

A using directive begins with the keyword using, followed by the keyword namespace, followed by a namespace name. It is an error if the name is not a previously defined namespace name. A using directive may appear in global, local, or namespace scope. It may not appear in a class scope.

These directives make all the names from a specific namespace visible without qualification. The short form names can be used from the point of the using directive to the end of the scope in which the using directive appears.

Warning

Providing a using directive for namespaces, such as std, that our application does not control reintroduces all the name collision problems inherent in using multiple libraries.

using Directives and Scope

The scope of names introduced by a using directive is more complicated than the scope of names in using declarations. As we've seen, a using declaration puts the name in the same scope as that of the using declaration itself. It is as if the using declaration declares a local alias for the namespace member.

A using directive does not declare local aliases. Rather, it has the effect of lifting the namespace members into the nearest scope that contains both the namespace itself and the using directive.

This difference in scope between a using declaration and a using directive stems directly from how these two facilities work. In the case of a using declaration, we are simply making name directly accessible in the local scope. In contrast, a using directive makes the entire contents of a namespace available In general, a namespace might include definitions that cannot appear in a local scope. As a consequence, a using directive is treated as if it appeared in the nearest enclosing namespace scope.

In the simplest case, assume we have a namespace A and a function f, both defined at global scope. If f has a using directive for A, then in f it will be as if the names in A appeared in the global scope prior to the definition of f:

Click here to view code image

using Directives Example

Let's look at an example:

The using directive in manip makes all the names in blip directly accessible; code inside manip can refer to the names of these members, using their short form.

The members of blip appear as if they were defined in the scope in which both blip and manip are defined. Assuming manip is defined at global scope, then the members of blip appear as if they were declared in global scope.

When a namespace is injected into an enclosing scope, it is possible for names in the namespace to conflict with other names defined in that (enclosing) scope. For example, inside manip, the blip member j conflicts with the global object named j. Such conflicts are permitted, but to use the name, we must explicitly indicate which version is wanted. Any unqualified use of j within manip is ambiguous.

To use a name such as j, we must use the scope operator to indicate which name is wanted. We would write :: j to obtain the variable defined in global scope. To use the j defined in blip, we must use its qualified name, blip::j.

Because the names are in different scopes, local declarations within manip may hide some of the namespace member names. The local variable k hides the namespace member blip::k. Referring to k within manip is not ambiguous; it refers to the local variable k.

Headers and using Declarations or Directives

A header that has a using directive or declaration at its top-level scope injects names into every file that includes the header. Ordinarily, headers should define only the names that are part of its interface, not names used in its own implementation. As a result, header files should not contain using directives or using declarations except inside functions or namespaces (§ 3.1, p. 83).

Caution: Avoid using Directives

using directives, which inject all the names from a namespace, are deceptively simple to use: With only a single statement, all the member names of a namespace are suddenly visible. Although this approach may seem simple, it can introduce its own problems. If an application uses many libraries, and if the names within these libraries are made visible with using directives, then we are back to square one, and the global namespace pollution problem reappears.

Moreover, it is possible that a working program will fail to compile when a new version of the library is introduced. This problem can arise if a new version introduces a name that conflicts with a name that the application is using.

Another problem is that ambiguity errors caused by using directives are detected only at the point of use. This late detection means that conflicts can arise long after introducing a particular library. If the program begins using a new part of the library, previously undetected collisions may arise.

Rather than relying on a using directive, it is better to use a using declaration for each namespace name used in the program. Doing so reduces the number of names injected into the namespace. Ambiguity errors caused by using declarations are detected at the point of declaration, not use, and so are easier to find and fix.

qiT

One place where using directives are useful is in the implementation files of the namespace itself.

Exercises Section 18.2.2

Exercise 18.15: Explain the differences between using declarations and directives.

Exercise 18.16: Explain the following code assuming using declarations for all the members of namespace Exercise are located at the location labeled position 1. What if they appear at position 2 instead? Now answer the same question but replace the using declarations with a using directive for namespace Exercise.

Click here to view code image

```
namespace Exercise {
    int ivar = 0;
    double dvar = 0;
    const int limit = 1000;
}
int ivar = 0;
// position I
void manip() {
    // position 2
    double dvar = 3.1416;
    int iobj = limit + 1;
    ++ivar;
    ++::ivar;
}
```

Exercise 18.17: Write code to test your answers to the previous question.

18.2.3. Classes, Namespaces, and Scope

Name lookup for names used inside a namespace follows the normal lookup rules: The search looks outward through the enclosing scopes. An enclosing scope might be one or more nested namespaces, ending in the all-encompassing global namespace. Only names that have been declared before the point of use that are in blocks that are still open are considered:

Click here to view code image

When a class is wrapped in a namespace, the normal lookup still happens: When a name is used by a member function, look for that name in the member first, then within the class (including base classes), then look in the enclosing scopes, one or more of which might be a namespace:

With the exception of member function definitions that appear inside the class body (§ 7.4.1, p. 283), scopes are always searched upward; names must be declared before they can be used. Hence, the return in £2 will not compile. It attempts to reference the name h from namespace A, but h has not yet been defined. Had that name been defined in A before the definition of C1, the use of h would be legal. Similarly, the use of h inside £3 is okay, because £3 is defined after A::h.

The order in which scopes are examined to find a name can be inferred from the qualified name of a function. The qualified name indicates, in reverse order, the scopes that are searched.

The qualifiers A::C1::f3 indicate the reverse order in which the class scopes and namespace scopes are to be searched. The first scope searched is that of the function f3. Then the class scope of its enclosing class C1 is searched. The scope of the namespace A is searched last before the scope containing the definition of f3 is examined.

Argument-Dependent Lookup and Parameters of Class Type

Consider the following simple program:

```
std::string s;
std::cin >> s;

As we know, this call is equivalent to (§ 14.1, p. 553):
    operator>>(std::cin, s);
```

This operator>> function is defined by the string library, which in turn is defined in the std namespace. Yet we can we call operator>> without an std:: qualifier and without a using declaration.

We can directly access the output operator because there is an important exception to the rule that names defined in a namespace are hidden. When we pass an object of a class type to a function, the compiler searches the namespace in which the argument's class is defined *in addition* to the normal scope lookup. This exception also applies for calls that pass pointers or references to a class type.

In this example, when the compiler sees the "call" to operator>>, it looks for a

matching function in the current scope, including the scopes enclosing the output statement. In addition, because the >> expression has parameters of class type, the compiler also looks in the namespace(s) in which the types of cin and s are defined. Thus, for this call, the compiler looks in the std namespace, which defines the istream and string types. When it searches std, the compiler finds the string output operator function.

This exception in the lookup rules allows nonmember functions that are conceptually part of the interface to a class to be used without requiring a separate using declaration. In the absence of this exception to the lookup rules, either we would have to provide an appropriate using declaration for the output operator:

Click here to view code image

```
using std::operator>>; // needed to allow cin >> s
```

or we would have to use the function-call notation in order to include the namespace qualifer:

Click here to view code image

```
std::operator>>(std::cin, s); // ok: explicitly use std::>>
```

There would be no way to use operator syntax. Either of these declarations is awkward and would make simple uses of the IO library more complicated.

Lookup and std::move and std::forward

Many, perhaps even most, C++ programmers never have to think about argument-dependent lookup. Ordinarily, if an application defines a name that is also defined in the library, one of two things is true: Either normal overloading determines (correctly) whether a particular call is intended for the application version or the one from the library, or the application never intends to use the library function.

Now consider the library move and forward functions. Both of these functions are template functions, and the library defines versions of them that have a single rvalue reference function parameter. As we've seen, in a function template, an rvalue reference parameter can match any type (§ 16.2.6, p. 690). If our application defines a function named move that takes a single parameter, then—no matter what type the parameter has—the application's version of move will collide with the library version. Similarly for forward.

As a result, name collisions with move (and forward) are more likely than collisions with other library functions. In addition, because move and forward do very specialized type manipulations, the chances that an application specifically wants to override the behavior of these functions are pretty small.

The fact that collisions are more likely—and are less likely to be intentional—explains why we suggest always using the fully qualified versions of these names (§

12.1.5, p. 470). So long as we write std::move rather than move, we know that we will get the version from the standard library.

Friend Declarations and Argument-Dependent Lookup

Recall that when a class declares a friend, the friend declaration does not make the friend visible (§ 7.2.1, p. 270). However, an otherwise undeclared class or function that is first named in a friend declaration is assumed to be a member of the closest enclosing namespace. The combination of this rule and argument-dependent lookup can lead to surprises:

Click here to view code image

Here, both f and f2 are members of namespace A. Through argument-dependent lookup, we can call f even if there is no additional declaration for f:

Click here to view code image

```
int main()
{
    A::C cobj;
    f(cobj);    // ok: finds A::f through the friend declaration in A::C
    f2();    // error: A::f2 not declared
}
```

Because f takes an argument of a class type, and f is implicitly declared in the same namespace as C, f is found when called. Because f has no parameter, it will not be found.

Exercises Section 18.2.3

Exercise 18.18: Given the following typical definition of swap § 13.3 (p. 517), determine which version of swap is used if mem1 is a string. What if mem1 is an int? Explain how name lookup works in both cases.

```
void swap(T v1, T v2)
{
    using std::swap;
    swap(v1.mem1, v2.mem1);
    // swap remaining members of type T
}
Exercise 18.19: What if the call to swap was std::swap(v1.mem1, v2.mem1)?
```

18.2.4. Overloading and Namespaces

Namespaces have two impacts on function matching (§ 6.4, p. 233). One of these should be obvious: A using declaration or directive can add functions to the candidate set. The other is much more subtle.

Argument-Dependent Lookup and Overloading

As we saw in the previous section, name lookup for functions that have class-type arguments includes the namespace in which each argument's class is defined. This rule also impacts how we determine the candidate set. Each namespace that defines a class used as an argument (and those that define its base classes) is searched for candidate functions. Any functions in those namespaces that have the same name as the called function are added to the candidate set. These functions are added even though they otherwise are not visible at the point of the call:

Click here to view code image

```
namespace NS {
    class Quote { /* ... */ };
    void display(const Quote&) { /* ... */ }
}
// Bulk_item's base class is declared in namespace NS
class Bulk_item : public NS::Quote { /* ... */ };
int main() {
    Bulk_item book1;

    display(book1);
    return 0;
}
```

The argument we passed to display has class type Bulk_item. The candidate functions for the call to display are not only the functions with declarations that are in scope where display is called, but also the functions in the namespace where Bulk_item and its base class, Quote, are declared. The function display(const Quote&) declared in namespace NS is added to the set of candidate functions.

Overloading and using Declarations

To understand the interaction between using declarations and overloading, it is important to remember that a using declaration declares a name, not a specific function (§ 15.6, p. 621):

Click here to view code image

```
using NS::print(int); // error: cannot specify a parameter list using NS::print; // ok: using declarations specify names only
```

When we write a using declaration for a function, all the versions of that function are brought into the current scope.

A using declaration incorporates all versions to ensure that the interface of the namespace is not violated. The author of a library provided different functions for a reason. Allowing users to selectively ignore some but not all of the functions from a set of overloaded functions could lead to surprising program behavior.

The functions introduced by a using declaration overload any other declarations of the functions with the same name already present in the scope where the using declaration appears. If the using declaration appears in a local scope, these names hide existing declarations for that name in the outer scope. If the using declaration introduces a function in a scope that already has a function of the same name with the same parameter list, then the using declaration is in error. Otherwise, the using declaration defines additional overloaded instances of the given name. The effect is to increase the set of candidate functions.

Overloading and using Directives

A using directive lifts the namespace members into the enclosing scope. If a namespace function has the same name as a function declared in the scope at which the namespace is placed, then the namespace member is added to the overload set:

```
namespace libs_R_us {
    extern void print(int);
    extern void print(double);
}
// ordinary declaration
void print(const std::string &);
// this using directive adds names to the candidate set for calls to print:
using namespace libs_R_us;
// the candidates for calls to print at this point in the program are:
// print(int) from libs_R_us
// print(double) from libs_R_us
```

```
// print(const std::string &) declared explicitly
void fooBar(int ival)
{
    print("Value: "); // calls global print(const string &)
    print(ival); // calls libs_R_us::print(int)
}
```

Differently from how using declarations work, it is not an error if a using directive introduces a function that has the same parameters as an existing function. As with other conflicts generated by using directives, there is no problem unless we try to call the function without specifying whether we want the one from the namespace or from the current scope.

Overloading across Multiple using Directives

If many using directives are present, then the names from each namespace become part of the candidate set:

Click here to view code image

```
namespace AW {
    int print(int);
}
namespace Primer {
    double print(double);
}
// using directives create an overload set of functions from different namespaces
using namespace AW;
using namespace Primer;
long double print(long double);
int main() {
    print(1); // calls AW::print(int)
    print(3.1); // calls Primer::print(double)
    return 0;
}
```

The overload set for the function print in global scope contains the functions print(int), print(double), and print(long double). These functions are all part of the overload set considered for the function calls in main, even though these functions were originally declared in different namespace scopes.

Exercises Section 18.2.4

Exercise 18.20: In the following code, determine which function, if any, matches the call to compute. List the candidate and viable functions. What type conversions, if any, are applied to the argument to match the parameter in each viable function?

```
namespace primerLib {
    void compute();
    void compute(const void *);
}
using primerLib::compute;
void compute(int);
void compute(double, double = 3.4);
void compute(char*, char* = 0);
void f()
{
    compute(0);
}
```

What would happen if the using declaration were located in main before the call to compute? Answer the same questions as before.

18.3. Multiple and Virtual Inheritance

Multiple inheritance is the ability to derive a class from more than one direct base class (§ 15.2.2, p. 600). A multiply derived class inherits the properties of all its parents. Although simple in concept, the details of intertwining multiple base classes can present tricky design-level and implementation-level problems.

To explore multiple inheritance, we'll use a pedagogical example of a zoo animal hierarchy. Our zoo animals exist at different levels of abstraction. There are the individual animals, distinguished by their names, such as Ling-ling, Mowgli, and Balou. Each animal belongs to a species; Ling-Ling, for example, is a giant panda. Species, in turn, are members of families. A giant panda is a member of the bear family. Each family, in turn, is a member of the animal kingdom—in this case, the more limited kingdom of a particular zoo.

We'll define an abstract ZooAnimal class to hold information that is common to all the zoo animals and provides the most general interface. The Bear class will contain information that is unique to the Bear family, and so on.

In addition to the ZooAnimal classes, our application will contain auxiliary classes that encapsulate various abstractions such as endangered animals. In our implementation of a Panda class, for example, a Panda is multiply derived from Bear and Endangered.

18.3.1. Multiple Inheritance

The derivation list in a derived class can contain more than one base class:

```
class Bear : public ZooAnimal {
```

```
class Panda : public Bear, public Endangered { /* ... */ };
```

Each base class has an optional access specifier (§ 15.5, p. 612). As usual, if the access specifier is omitted, the specifier defaults to private if the class keyword is used and to public if struct is used (§ 15.5, p. 616).

As with single inheritance, the derivation list may include only classes that have been defined and that were not defined as final (§ 15.2.2, p. 600). There is no language-imposed limit on the number of base classes from which a class can be derived. A base class may appear only once in a given derivation list.

Multiply Derived Classes Inherit State from Each Base Class

Under multiple inheritance, an object of a derived class contains a subobject for each of its base classes (§ 15.2.2, p. 597). For example, as illustrated in Figure 18.2, a Panda object has a Bear part (which itself contains a ZooAnimal part), an Endangered class part, and the nonstatic data members, if any, declared within the Panda class.

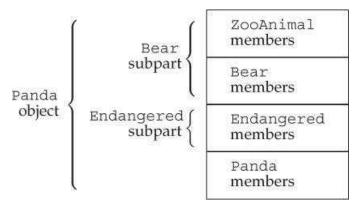

Figure 18.2. Conceptual Structure of a Panda Object

Derived Constructors Initialize All Base Classes

Constructing an object of derived type constructs and initializes all its base subobjects. As is the case for inheriting from a single base class (§ 15.2.2, p. 598), a derived type's constructor initializer may initialize only its direct base classes:

The constructor initializer list may pass arguments to each of the direct base classes. The order in which base classes are constructed depends on the order in which they appear in the class derivation list. The order in which they appear in the constructor initializer list is irrelevant. A Panda object is initialized as follows:

- ZooAnimal, the ultimate base class up the hierarchy from Panda's first direct base class, Bear, is initialized first.
- Bear, the first direct base class, is initialized next.
- Endangered, the second direct base, is initialized next.
- Panda, the most derived part, is initialized last.

Inherited Constructors and Multiple Inheritance

Under the new standard, a derived class can inherit its constructors from one or more of its base classes (§ 15.7.4, p. 628). It is an error to inherit the same constructor (i.e., one with the same parameter list) from more than one base class:

Click here to view code image

```
struct Base1 {
    Base1() = default;
    Base1(const std::string&);
    Base1(std::shared_ptr<int>);
};

struct Base2 {
    Base2() = default;
    Base2(const std::string&);
    Base2(int);
};

// error: D1 attempts to inherit D1::D1 (const string&) from both base classes
struct D1: public Base1, public Base2 {
    using Base1::Base1; // inherit constructors from Base1
    using Base2::Base2; // inherit constructors from Base2
};
```

A class that inherits the same constructor from more than one base class must define its own version of that constructor:

```
struct D2: public Base1, public Base2 {
   using Base1::Base1; // inherit constructors from Base1
   using Base2::Base2; // inherit constructors from Base2
   // D2 must define its own constructor that takes a string
   D2(const string &s): Base1(s), Base2(s) {
   D2() = default; // needed once D2 defines its own constructor
```

};

Destructors and Multiple Inheritance

As usual, the destructor in a derived class is responsible for cleaning up resources allocated by that class only—the members and all the base class(es) of the derived class are automatically destroyed. The synthesized destructor has an empty function body.

Destructors are always invoked in the reverse order from which the constructors are run. In our example, the order in which the destructors are called is ~Panda, ~Endangered, ~Bear, ~ZooAnimal.

Copy and Move Operations for Multiply Derived Classes

As is the case for single inheritance, classes with multiple bases that define their own copy/move constructors and assignment operators must copy, move, or assign the whole object (§ 15.7.2, p. 623). The base parts of a multiply derived class are automatically copied, moved, or assigned only if the derived class uses the synthesized versions of these members. In the synthesized copy-control members, each base class is implicitly constructed, assigned, or destroyed, using the corresponding member from that base class.

For example, assuming that Panda uses the synthesized members, then the initialization of ling ling:

Click here to view code image

```
Panda ying_yang("ying_yang");
Panda ling_ling = ying_yang;  // uses the copy constructor
```

will invoke the Bear copy constructor, which in turn runs the ZooAnimal copy constructor before executing the Bear copy constructor. Once the Bear portion of ling_ling is constructed, the Endangered copy constructor is run to create that part of the object. Finally, the Panda copy constructor is run. Similarly, for the synthesized move constructor.

The synthesized copy-assignment operator behaves similarly to the copy constructor. It assigns the Bear (and through Bear, the ZooAnimal) parts of the object first. Next, it assigns the Endangered part, and finally the Panda part. Move assignment behaves similarly.

18.3.2. Conversions and Multiple Base Classes

Under single inheritance, a pointer or a reference to a derived class can be converted automatically to a pointer or a reference to an accessible base class (§ 15.2.2, p. 597, and § 15.5, p. 613). The same holds true with multiple inheritance. A pointer or

reference to any of an object's (accessible) base classes can be used to point or refer to a derived object. For example, a pointer or reference to ZooAnimal, Bear, or Endangered can be bound to a Panda object:

Click here to view code image

```
// operations that take references to base classes of type Panda
void print(const Bear&);
void highlight(const Endangered&);
ostream& operator<<(ostream&, const ZooAnimal&);

Panda ying_yang("ying_yang");

print(ying_yang); // passes Panda to a reference to Bear
highlight(ying_yang); // passes Panda to a reference to Endangered
cout << ying_yang << endl; // passes Panda to a reference to ZooAnimal</pre>
```

Exercises Section 18.3.1

Exercise 18.21: Explain the following declarations. Identify any that are in error and explain why they are incorrect:

```
(a) class CADVehicle : public CAD, Vehicle \{\ldots\};
```

- (b) class DblList: public List, public List { ... };
- (c) class iostream: public istream, public ostream $\{ \ldots \};$

Exercise 18.22: Given the following class hierarchy, in which each class defines a default constructor:

Click here to view code image

```
class A { ... };
class B : public A { ... };
class C : public B { ... };
class X { ... };
class Y { ... };
class Z : public X, public Y { ... };
class MI : public C, public Z { ... };
```

what is the order of constructor execution for the following definition?

```
MI mi;
```

The compiler makes no attempt to distinguish between base classes in terms of a derived-class conversion. Converting to each base class is equally good. For example, if there was an overloaded version of print:

```
void print(const Bear&);
```

```
void print(const Endangered&);
```

an unqualified call to print with a Panda object would be a compile-time error:

Click here to view code image

Lookup Based on Type of Pointer or Reference

As with single inheritance, the static type of the object, pointer, or reference determines which members we can use (§ 15.6, p. 617). If we use a ZooAnimal pointer, only the operations defined in that class are usable. The Bear-specific, Panda-specific, and Endangered portions of the Panda interface are invisible. Similarly, a Bear pointer or reference knows only about the Bear and ZooAnimal members; an Endangered pointer or reference is limited to the Endangered members.

As an example, consider the following calls, which assume that our classes define the virtual functions listed in Table 18.1:

Click here to view code image

When a Panda is used via an Endangered pointer or reference, the Panda-specific and Bear portions of the Panda interface are invisible:

Table 18.1. Virtual Functions in the ZooAnimal/Endangered Classes

Function	Class Defining Own Version
print	ZooAnimal::ZooAnimal
	Bear::Bear
	Endangered::Endangered
	Panda::Panda
highlight	Endangered::Endangered
	Panda::Panda
toes	Bear::Bear
	Panda::Panda
cuddle	Panda::Panda
destructor	ZooAnimal::ZooAnimal
	Endangered::Endangered

18.3.3. Class Scope under Multiple Inheritance

Under single inheritance, the scope of a derived class is nested within the scope of its direct and indirect base classes (§ 15.6, p. 617). Lookup happens by searching up the inheritance hierarchy until the given name is found. Names defined in a derived class hide uses of that name inside a base.

Under multiple inheritance, this same lookup happens *simultaneously* among all the direct base classes. If a name is found through more than one base class, then use of that name is ambiguous.

Exercises Section 18.3.2

Exercise 18.23: Using the hierarchy in exercise 18.22 along with class D defined below, and assuming each class defines a default constructor, which, if any, of the following conversions are not permitted?

```
class D : public X, public C { ... };
D *pd = new D;

(a) X *px = pd;
(b) A *pa = pd;
(c) B *pb = pd;
(d) C *pc = pd;
```

Exercise 18.24: On page 807 we presented a series of calls made through a Bear pointer that pointed to a Panda object. Explain each call assuming we used a ZooAnimal pointer pointing to a Panda object instead.

Exercise 18.25: Assume we have two base classes, Basel and Basel, each of which defines a virtual member named print and a virtual destructor. From these base classes we derive the following classes, each of which redefines the print function:

Click here to view code image

```
class D1 : public Base1 \{ /* \dots */ \}; class D2 : public Base2 \{ /* \dots */ \};
class MI : public D1, public D2 { /* ... */ };
```

Using the following pointers, determine which function is used in each call:

```
Base1 *pb1 = new MI;
Base2 *pb2 = new MI;
D1 *pd1 = new MI;
D2 *pd2 = new MI;
(a) pb1->print();
(b) pd1->print();
(c) pd2->print();
(d) delete pb2;
(e) delete pd1;
(f) delete pd2;
```

In our example, if we use a name through a Panda object, pointer, or reference, both the Endangered and the Bear/ZooAnimal subtrees are examined in parallel. If the name is found in more than one subtree, then the use of the name is ambiguous. It is perfectly legal for a class to inherit multiple members with the same name. However, if we want to use that name, we must specify which version we want to use.

Warning

When a class has multiple base classes, it is possible for that derived class to inherit a member with the same name from two or more of its base classes. Unqualified uses of that name are ambiguous.

For example, if both ZooAnimal and Endangered define a member named max weight, and Panda does not define that member, this call is an error:

Click here to view code image

```
double d = ying_yang.max_weight();
```

The derivation of Panda, which results in Panda having two members named max_weight, is perfectly legal. The derivation generates a potential ambiguity. That ambiguity is avoided if no Panda object ever calls max_weight. The error would also be avoided if each call to max weight specifically indicated which version to run -ZooAnimal::max weight Or Endangered::max weight. An error results only

if there is an ambiguous attempt to use the member.

The ambiguity of the two inherited <code>max_weight</code> members is reasonably obvious. It might be more surprising to learn that an error would be generated even if the two inherited functions had different parameter lists. Similarly, it would be an error even if the <code>max_weight</code> function were <code>private</code> in one class and <code>public</code> or <code>protected</code> in the other. Finally, if <code>max_weight</code> were defined in <code>Bear</code> and not in <code>ZooAnimal</code>, the call would still be in error.

As always, name lookup happens before type checking (§ 6.4.1, p. 234). When the compiler finds max_weight in two different scopes, it generates an error noting that the call is ambiguous.

The best way to avoid potential ambiguities is to define a version of the function in the derived class that resolves the ambiguity. For example, we should give our Panda class a max_weight function that resolves the ambiguity:

Click here to view code image

Exercises Section 18.3.3

Exercise 18.26: Given the hierarchy in the box on page 810, why is the following call to print an error? Revise MI to allow this call to print to compile and execute correctly.

```
MI mi;
mi.print(42);
```

Exercise 18.27: Given the class hierarchy in the box on page 810 and assuming we add a function named foo to MI as follows:

```
int ival;
double dval;

void MI::foo(double cval)
{
    int dval;
    // exercise questions occur here
}
```

- (a) List all the names visible from within MI::foo.
- (b) Are any names visible from more than one base class?
- (c) Assign to the local instance of dval the sum of the dval member of Basel and the dval member of Derived.
- (d) Assign the value of the last element in MI::dvec to Base2::fval.

(e) Assign cval from Basel to the first character in sval from Derived.

```
Code for Exercises to Section 18.3.3
Click here to view code image
   struct Base1 {
       void print(int) const;  // public by default
   protected:
               ival;
       int
       double dval;
       char cval;
   private:
       int *id;
   };
   struct Base2 {
                                         // public by default
       void print(double) const;
   protected:
       double fval;
   private:
       double dval;
   struct Derived : public Basel {
       void print(std::string) const; // public by default
   protected:
       std::string sval;
       double dval;
   };
   struct MI : public Derived, public Base2 {
       void print(std::vector<double>); // public by default
   protected:
       int
                             *ival;
       std::vector<double>
                             dvec;
   };
```

18.3.4. Virtual Inheritance

Although the derivation list of a class may not include the same base class more than once, a class can inherit from the same base class more than once. It might inherit the same base indirectly from two of its own direct base classes, or it might inherit a particular class directly and indirectly through another of its base classes.

As an example, the IO library istream and ostream classes each inherit from a common abstract base class named basic_ios. That class holds the stream's buffer and manages the stream's condition state. The class iostream, which can both read and write to a stream, inherits directly from both istream and ostream. Because

both types inherit from basic_ios, iostream inherits that base class twice, once through istream and once through ostream.

By default, a derived object contains a separate subpart corresponding to each class in its derivation chain. If the same base class appears more than once in the derivation, then the derived object will have more than one subobject of that type.

This default doesn't work for a class such as iostream. An iostream object wants to use the same buffer for both reading and writing, and it wants its condition state to reflect both input and output operations. If an iostream object has two copies of its basic_ios class, this sharing isn't possible.

In C++ we solve this kind of problem by using **virtual inheritance**. Virtual inheritance lets a class specify that it is willing to share its base class. The shared base-class subobject is called a **virtual base class**. Regardless of how often the same virtual base appears in an inheritance hierarchy, the derived object contains only one, shared subobject for that virtual base class.

A Different Panda Class

In the past, there was some debate as to whether panda belongs to the raccoon or the bear family. To reflect this debate, we can change Panda to inherit from both Bear and Raccoon. To avoid giving Panda two ZooAnimal base parts, we'll define Bear and Raccoon to inherit virtually from ZooAnimal. Figure 18.3 illustrates our new hierarchy.

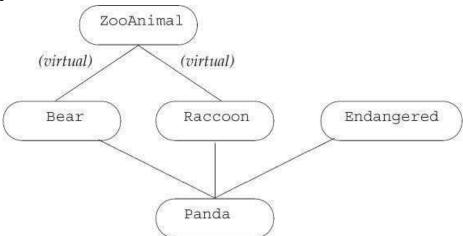

Figure 18.3. Virtual Inheritance Panda Hierarchy

Looking at our new hierarchy, we'll notice a nonintuitive aspect of virtual inheritance. The virtual derivation has to be made before the need for it appears. For example, in our classes, the need for virtual inheritance arises only when we define Panda. However, if Bear and Raccoon had not specified virtual on their derivation from ZooAnimal, the designer of the Panda class would be out of luck.

In practice, the requirement that an intermediate base class specify its inheritance

as virtual rarely causes any problems. Ordinarily, a class hierarchy that uses virtual inheritance is designed at one time either by one individual or by a single project design group. It is exceedingly rare for a class to be developed independently that needs a virtual base in one of its base classes and in which the developer of the new base class cannot change the existing hierarchy.

Note

Virtual derivation affects the classes that subsequently derive from a class with a virtual base; it doesn't affect the derived class itself.

Using a Virtual Base Class

We specify that a base class is virtual by including the keyword virtual in the derivation list:

Click here to view code image

```
// the order of the keywords public and virtual is not significant
class Raccoon : public virtual ZooAnimal { /* ... */ };
class Bear : virtual public ZooAnimal { /* ... */ };
```

Here we've made ZooAnimal a virtual base class of both Bear and Raccoon.

The virtual specifier states a willingness to share a single instance of the named base class within a subsequently derived class. There are no special constraints on a class used as a virtual base class.

We do nothing special to inherit from a class that has a virtual base:

Click here to view code image

Here Panda inherits ZooAnimal through both its Raccoon and Bear base classes. However, because those classes inherited virtually from ZooAnimal, Panda has only one ZooAnimal base subpart.

Normal Conversions to Base Are Supported

An object of a derived class can be manipulated (as usual) through a pointer or a reference to an accessible base-class type regardless of whether the base class is virtual. For example, all of the following Panda base-class conversions are legal:

```
void dance(const Bear&);
void rummage(const Raccoon&);
ostream& operator<<(ostream&, const ZooAnimal&);
Panda ying_yang;
dance(ying_yang); // ok: passes Panda object as a Bear
rummage(ying_yang); // ok: passes Panda object as a Raccoon
cout << ying_yang; // ok: passes Panda object as a ZooAnimal</pre>
```

Visibility of Virtual Base-Class Members

Because there is only one shared subobject corresponding to each shared virtual base, members in that base can be accessed directly and unambiguously. Moreover, if a member from the virtual base is overridden along only one derivation path, then that overridden member can still be accessed directly. If the member is overridden by more than one base, then the derived class generally must define its own version as well.

For example, assume class B defines a member named x; class D1 inherits virtually from B as does class D2; and class D inherits from D1 and D2. From the scope of D, x is visible through both of its base classes. If we use x through a D object, there are three possibilities:

- If x is not defined in either D1 or D2 it will be resolved as a member in B; there is no ambiguity. A D object contains only one instance of x.
- If x is a member of B and also a member in one, but not both, of D1 and D2, there is again no ambiguity—the version in the derived class is given precedence over the shared virtual base class, B.
- If x is defined in both D1 and D2, then direct access to that member is ambiguous.

As in a nonvirtual multiple inheritance hierarchy, ambiguities of this sort are best resolved by the derived class providing its own instance of that member.

Exercises Section 18.3.4

Exercise 18.28: Given the following class hierarchy, which inherited members can be accessed without qualification from within the VMI class? Which require qualification? Explain your reasoning.

```
struct Base {
    void bar(int); // public by default
protected:
    int ival;
};
struct Derived1 : virtual public Base {
    void bar(char); // public by default
```

```
void foo(char);
protected:
    char cval;
};
struct Derived2 : virtual public Base {
    void foo(int); // public by default
protected:
    int ival;
    char cval;
};
class VMI : public Derived1, public Derived2 { };
```

18.3.5. Constructors and Virtual Inheritance

In a virtual derivation, the virtual base is initialized by the *most derived constructor*. In our example, when we create a Panda object, the Panda constructor alone controls how the ZooAnimal base class is initialized.

To understand this rule, consider what would happen if normal initialization rules applied. In that case, a virtual base class might be initialized more than once. It would be initialized along each inheritance path that contains that virtual base. In our ZooAnimal example, if normal initialization rules applied, both Bear and Raccoon would initialize the ZooAnimal part of a Panda object.

Of course, each class in the hierarchy might at some point be the "most derived" object. As long as we can create independent objects of a type derived from a virtual base, the constructors in that class must initialize its virtual base. For example, in our hierarchy, when a Bear (or a Raccoon) object is created, there is no further derived type involved. In this case, the Bear (or Raccoon) constructors directly initialize their ZooAnimal base as usual:

Click here to view code image

When a Panda is created, it is the most derived type and controls initialization of the shared ZooAnimal base. Even though ZooAnimal is not a direct base of Panda, the Panda constructor initializes ZooAnimal:

How a Virtually Inherited Object Is Constructed

The construction order for an object with a virtual base is slightly modified from the normal order: The virtual base subparts of the object are initialized first, using initializers provided in the constructor for the most derived class. Once the virtual base subparts of the object are constructed, the direct base subparts are constructed in the order in which they appear in the derivation list.

For example, when a Panda object is created:

- The (virtual base class) ZooAnimal part is constructed first, using the initializers specified in the Panda constructor initializer list.
- The Bear part is constructed next.
- The Raccoon part is constructed next.
- The third direct base, Endangered, is constructed next.
- Finally, the Panda part is constructed.

If the Panda constructor does not explicitly initialize the ZooAnimal base class, then the ZooAnimal default constructor is used. If ZooAnimal doesn't have a default constructor, then the code is in error.

Note

Virtual base classes are always constructed prior to nonvirtual base classes regardless of where they appear in the inheritance hierarchy.

Constructor and Destructor Order

A class can have more than one virtual base class. In that case, the virtual subobjects are constructed in left-to-right order as they appear in the derivation list. For example, in the following whimsical TeddyBear derivation, there are two virtual base classes: ToyAnimal, a direct virtual base, and ZooAnimal, which is a virtual base class of Bear:

The direct base classes are examined in declaration order to determine whether there are any virtual base classes. If so, the virtual bases are constructed first, followed by the nonvirtual base-class constructors in declaration order. Thus, to create a TeddyBear, the constructors are invoked in the following order:

Click here to view code image

The same order is used in the synthesized copy and move constructors, and members are assigned in this order in the synthesized assignment operators. As usual, an object is destroyed in reverse order from which it was constructed. The TeddyBear part will be destroyed first and the ZooAnimal part last.

Exercises Section 18.3.5

Exercise 18.29: Given the following class hierarchy:

Click here to view code image

```
class Class { ... };
class Base : public Class { ... };
class D1 : virtual public Base { ... };
class D2 : virtual public Base { ... };
class MI : public D1, public D2 { ... };
class Final : public MI, public Class { ... };
```

- (a) In what order are constructors and destructors run on a Final object?
- (b) A Final object has how many Base parts? How many Class parts?
- **(c)** Which of the following assignments is a compile-time error?

```
Base *pb; Class *pc; MI *pmi; D2 *pd2;
(a) pb = new Class;
(b) pc = new Final;
(c) pmi = pb;
(d) pd2 = pmi;
```

Exercise 18.30: Define a default constructor, a copy constructor, and a constructor that has an int parameter in Base. Define the same three constructors in each derived class. Each constructor should use its argument to initialize its Base part.

Chapter Summary

C++ is used to solve a wide range of problems—from those solvable in a few hours' time to those that take years of development by large teams. Some features in C++ are most applicable in the context of large-scale problems: exception handling, namespaces, and multiple or virtual inheritance.

Exception handling lets us separate the error-detection part of the program from the error-handling part. When an exception is thrown, the current executing function is suspended and a search is started to find the nearest matching catch clause. Local variables defined inside functions that are exited while searching for a catch clause are destroyed as part of handling the exception.

Namespaces are a mechanism for managing large, complicated applications built from code produced by independent suppliers. A namespace is a scope in which objects, types, functions, templates, and other namespaces may be defined. The standard library is defined inside the namespace named std.

Conceptually, multiple inheritance is a simple notion: A derived class may inherit from more than one direct base class. The derived object consists of the derived part and a base part contributed by each of its base classes. Although conceptually simple, the details can be more complicated. In particular, inheriting from multiple base classes introduces new possibilities for name collisions and resulting ambiguous references to names from the base part of an object.

When a class inherits directly from more than one base class, it is possible that those classes may themselves share another base class. In such cases, the intermediate classes can opt to make their inheritance virtual, which states a willingness to share their virtual base class with other classes in the hierarchy that inherit virtually from that same base class. In this way there is only one copy of the shared virtual base in a subsequently derived class.

Defined Terms

catch-all A catch clause in which the exception declaration is (...). A catch-all clause catches an exception of any type. It is typically used to catch an exception that is detected locally in order to do local cleanup. The exception is then rethrown to another part of the program to deal with the underlying cause of the problem.

catch clause Part of the program that handles an exception. A catch clause consists of the keyword catch followed by an exception declaration and a block of statements. The code inside a catch does whatever is necessary to handle an exception of the type defined in its exception declaration.

constructor order Under nonvirtual inheritance, base classes are constructed in the order in which they are named in the class derivation list. Under virtual inheritance, the virtual base class(es) are constructed before any other bases. They are constructed in the order in which they appear in the derivation list of the derived type. Only the most derived type may initialize a virtual base; constructor initializers for that base that appear in the intermediate base classes are ignored.

exception declaration catch clause declaration that specifies the type of exception that the catch can handle. The declaration acts like a parameter list, whose single parameter is initialized by the exception object. If the exception specifier is a nonreference type, then the exception object is copied to the catch.

exception handling Language-level support for managing run-time anomalies. One independently developed section of code can detect and "raise" an exception that another independently developed part of the program can "handle." The error-detecting part of the program throws an exception; the error-handling part handles the exception in a catch clause of a try block.

exception object Object used to communicate between the throw and catch sides of an exception. The object is created at the point of the throw and is a copy of the thrown expression. The exception object exists until the last handler for the exception completes. The type of the object is the static type of the thrown expression.

file static Name local to a file that is declared with the static keyword. In C and pre-Standard versions of C++, file statics were used to declare objects that could be used in a single file only. File statics are deprecated in C++, having been superseded by the use of unnamed namespaces.

function try block Used to catch exceptions from a constructor initializer. The keyword try appears before the colon that starts the constructor initializer list (or before the open curly of the constructor body if the initizlier list is empty) and closes with one or more catch clauses that appear after the close curly of the constructor body.

global namespace The (implicit) namespace in each program that holds all global definitions.

handler Synonym for a catch clause.

inline namespace Members of a namespace designated as inline can be used as if they were members of an enclosing namespace.

multiple inheritance Class with more than one direct base class. The derived class inherits the members of all its base classes. A separate access specifier may be provided for each base class.

namespace Mechanism for gathering all the names defined by a library or other collection of programs into a single scope. Unlike other scopes in C++, a namespace scope may be defined in several parts. The namepsace may be opened and closed and reopened again in disparate parts of the program.

namespace alias Mechanism for defining a synonym for a given namespace:

```
namespace N1 = N;
```

defines $\mathtt{N1}$ as another name for the namespace named \mathtt{N} . A namespace can have multiple aliases; the namespace name or any of its aliases may be used interchangeably.

namespace pollution Occurs when all the names of classes and functions are placed in the global namespace. Large programs that use code written by multiple independent parties often encounter collisions among names if these names are global.

noexcept operator Operator that returns a bool indicating whether a given expression might throw an exception. The expression is unevaluated. The result is a constant expression. Its value is true if the expression does not contain a throw and calls only functions designated as nonthrowing; otherwise the result is false.

noexcept specification Keyword used to indicate whether a function throws. When noexcept follows a function's parameter list, it may be optionally followed by a parenthesized constant expression that must be convertible to bool. If the expression is omitted, or if it is true, the function throws no exceptions. An expression that is false or a function that has no exception specification may throw any exception.

nonthrowing specification An exception specification that promises that a function won't throw. If a nonthrowing functions does throw, terminate is called. Nonthrowing specifiers are noexcept without an argument or with an argument that evaluates as true and throw().

raise Often used as a synonym for throw. C++ programmers speak of "throwing" or "raising" an exception interchangably.

rethrow A throw that does not specify an expression. A rethrow is valid only from inside a catch clause, or in a function called directly or indirectly from a catch. Its effect is to rethrow the exception object that it received.

stack unwinding The process whereby the functions are exited in the search for a catch. Local objects constructed before the exception are destroyed before entering the corresponding catch.

terminate Library function that is called if an exception is not caught or if an exception occurs while a handler is in process. terminate ends the program.

throw e Expression that interrupts the current execution path. Each throw transfers control to the nearest enclosing catch clause that can handle the type of exception that is thrown. The expression e is copied into the exception object.

try block Block of statements enclosed by the keyword try and one or more catch clauses. If the code inside the try block raises an exception and one of the catch clauses matches the type of the exception, then the exception is handled by that catch. Otherwise, the exception is passed out of the try to a catch further up the call chain.

unnamed namespace Namespace that is defined without a name. Names defined in an unnamed namespace may be accessed directly without use of the scope operator. Each file has its own unique unnamed namespace. Names in an unnamed namespace are not visible outside that file.

using declaration Mechanism to inject a single name from a namespace into the current scope:

```
using std::cout;
```

makes the name cout from the namespace std available in the current scope. The name cout can subsequently be used without the std:: qualifier.

using directive Declaration of the form

```
using NS;
```

makes all the names in the namespace named NS available in the nearest scope containing both the using directive and the namespace itself.

virtual base class Base class that specifies virtual in its own derivation list. A virtual base part occurs only once in a derived object even if the same class appears as a virtual base more than once in the hierarchy. In nonvirtual inheritance a constructor may initialize only its direct base class(es). When a class is inherited virtually, that class is initialized by the most derived class, which therefore should include an initializer for all of its virtual parent(s).

virtual inheritance Form of multiple inheritance in which derived classes share a single copy of a base that is included in the hierarchy more than once.

:: operator Scope operator. Used to access names from a namespace or a class.

Chapter Summary

Defined Terms

The first three parts of this book discussed apects of C++ that most C++ programmers are likely to use at some point. In addition, C++ defines some features that are more specialized. Many programmers will never (or only rarely) need to use the features presented in this chapter.

C++ is intended for use in a wide variety of applications. As a result, it contains features that are particular to some applications and that need never be used by others. In this chapter we look at some of the less-commonly used features in the language.

19.1. Controlling Memory Allocation

Some applications have specialized memory allocation needs that cannot be met by the standard memory management facilities. Such applications need to take over the details of how memory is allocated, for example, by arranging for new to put objects into particular kinds of memory. To do so, they can overload the new and delete operators to control memory allocation.

19.1.1. Overloading new and delete

Although we say that we can "overload new and delete," overloading these operators is quite different from the way we overload other operators. In order to understand how we overload these operators, we first need to know a bit more about how new and delete expressions work.

When we use a new expression:

```
// new expressions
string *sp = new string("a value"); // allocate and initialize a string
```

```
string *arr = new string[10]; // allocate ten default initialized strings
```

three steps actually happen. First, the expression calls a library function named operator new (or operator new[]). This function allocates raw, untyped memory large enough to hold an object (or an array of objects) of the specified type. Next, the compiler runs the appropriate constructor to construct the object(s) from the specified initializers. Finally, a pointer to the newly allocated and constructed object is returned.

When we use a delete expression to delete a dynamically allocated object:

Click here to view code image

```
// destroy *sp and free the memory to which sp points
delete sp;
delete [] arr; // destroy the elements in the array and free the memory
```

two steps happen. First, the appropriate destructor is run on the object to which sp points or on the elements in the array to which arr points. Next, the compiler frees the memory by calling a library function named operator delete or operator delete[], respectively.

Applications that want to take control of memory allocation define their own versions of the operator new and operator delete functions. Even though the library contains definitions for these functions, we can define our own versions of them and the compiler won't complain about duplicate definitions. Instead, the compiler will use our version in place of the one defined by the library.

Warning

When we define the global operator new and operator delete functions, we take over responsibility for all dynamic memory allocation. These functions must be correct: They form a vital part of all processing in the program.

Applications can define operator new and operator delete functions in the global scope and/or as member functions. When the compiler sees a new or delete expression, it looks for the corresponding operator function to call. If the object being allocated (deallocated) has class type, the compiler first looks in the scope of the class, including any base classes. If the class has a member operator new or operator delete, that function is used by the new or delete expression. Otherwise, the compiler looks for a matching function in the global scope. If the compiler finds a user-defined version, it uses that function to execute the new or delete expression. Otherwise, the standard library version is used.

We can use the scope operator to force a new or delete expression to bypass a class-specific function and use the one from the global scope. For example, ::new will look only in the global scope for a matching operator new function. Similarly for ::delete.

The operator new and operator delete Interface

The library defines eight overloaded versions of operator new and delete functions. The first four support the versions of new that can throw a bad_alloc exception. The next four support nonthrowing versions of new:

Click here to view code image

The type nothrow_t is a struct defined in the new header. This type has no members. The new header also defines a const object named nothrow, which users can pass to signal they want the nonthrowing version of new (§ 12.1.2, p. 460). Like destructors, an operator delete must not throw an exception (§ 18.1.1, p. 774). When we overload these operators, we must specify that they will not throw, which we do through the noexcept exception specifier (§ 18.1.4, p. 779).

An application can define its own version of any of these functions. If it does so, it must define these functions in the global scope or as members of a class. When defined as members of a class, these operator functions are implicitly static (§ 7.6, p. 302). There is no need to declare them static explicitly, although it is legal to do so. The member new and delete functions must be static because they are used either before the object is constructed (operator new) or after it has been destroyed (operator delete). There are, therefore, no member data for these functions to manipulate.

An operator new or operator new[] function must have a return type of void* and its first parameter must have type size_t. That parameter may not have a default argument. The operator new function is used when we allocate an object; operator new[] is called when we allocate an array. When the compiler calls operator new, it initializes the size_t parameter with the number of bytes required to hold an object of the specified type; when it calls operator new[], it passes the number of bytes required to store an array of the given number of elements.

When we define our own operator new function, we can define additional parameters. A new expression that uses such functions must use the placement form

of new (§ 12.1.2, p. 460) to pass arguments to these additional parameters. Although generally we may define our version of operator new to have whatever parameters are needed, we may not define a function with the following form:

Click here to view code image

void *operator new(size_t, void*); // this version may not be redefined
This specific form is reserved for use by the library and may not be redefined.

An operator delete or operator delete[] function must have a void return type and a first parameter of type void*. Executing a delete expression calls the appropriate operator function and initializes its void* parameter with a pointer to the memory to free.

When operator delete or operator delete[] is defined as a class member, the function may have a second parameter of type size_t. If present, the additional parameter is initialized with the size in bytes of the object addressed by the first parameter. The size_t parameter is used when we delete objects that are part of an inheritance hierarchy. If the base class has a virtual destructor (§ 15.7.1, p. 622), then the size passed to operator delete will vary depending on the dynamic type of the object to which the deleted pointer points. Moreover, the version of the operator delete function that is run will be the one from the dynamic type of the object.

Terminology: new Expression versus operator new Function

The library functions operator new and operator delete are misleadingly named. Unlike other operator functions, such as operator=, these functions do not overload the new or delete expressions. In fact, we cannot redefine the behavior of the new and delete expressions.

A new expression always executes by calling an operator new function to obtain memory and then constructing an object in that memory. A delete expression always executes by destroying an object and then calling an operator delete function to free the memory used by the object.

By providing our own definitions of the operator new and operator delete functions, we can change how memory is allocated. However, we cannot change this basic meaning of the new and delete operators.

The malloc and free Functions

If you define your own global operator new and operator delete, those functions must allocate and deallocate memory somehow. Even if you define these functions in order to use a specialized memory allocator, it can still be useful for testing purposes to be able to allocate memory similarly to how the implementation

normally does so.

To this end, we can use functions named **malloc** and **free** that C++ inherits from C. These functions, are defined in cstdlib.

The malloc function takes a size_t that says how many bytes to allocate. It returns a pointer to the memory that it allocated, or 0 if it was unable to allocate the memory. The free function takes a void* that is a copy of a pointer that was returned from malloc and returns the associated memory to the system. Calling free(0) has no effect.

A simple way to write operator new and operator delete is as follows:

Click here to view code image

```
void *operator new(size_t size) {
    if (void *mem = malloc(size))
        return mem;
    else
        throw bad_alloc();
}
void operator delete(void *mem) noexcept { free(mem); }
and similarly for the other versions of operator new and operator delete.
```

Exercises Section 19.1.1

Exercise 19.1: Write your own operator new(size_t) function using malloc and use free to write the operator delete(void*) function.

Exercise 19.2: By default, the allocator class uses operator new to obtain storage and operator delete to free it. Recompile and rerun your StrVec programs (§ 13.5, p. 526) using your versions of the functions from the previous exercise.

19.1.2. Placement new Expressions

Although the operator new and operator delete functions are intended to be used by new expressions, they are ordinary functions in the library. As a result, ordinary code can call these functions directly.

In earlier versions of the language—before the allocator (§ 12.2.2, p. 481) class was part of the library—applications that wanted to separate allocation from initialization did so by calling operator new and operator delete. These functions behave analogously to the allocate and deallocate members of allocator. Like those members, operator new and operator delete functions allocate and deallocate memory but do not construct or destroy objects.

Differently from an allocator, there is no construct function we can call to

construct objects in memory allocated by operator new. Instead, we use the **placement new** form of new (§ 12.1.2, p. 460) to construct an object. As we've seen, this form of new provides extra information to the allocation function. We can use placement new to pass an address, in which case the placement new expression has the form

Click here to view code image

```
new (place_address) type
new (place_address) type (initializers)
new (place_address) type [size]
new (place_address) type [size] { braced initializer list }
```

where *place_address* must be a pointer and the *initializers* provide (a possibly empty) comma-separated list of initializers to use to construct the newly allocated object.

When called with an address and no other arguments, placement new uses operator new(size_t, void*) to "allocate" its memory. This is the version of operator new that we are not allowed to redefine (§ 19.1.1, p. 822). This function does not allocate any memory; it simply returns its pointer argument. The overall new expression then finishes its work by initializing an object at the given address. In effect, placement new allows us to construct an object at a specific, preallocated memory address.

Note

When passed a single argument that is a pointer, a placement new expression constructs an object but does not allocate memory.

Although in many ways using placement new is analogous to the construct member of an allocator, there is one important difference. The pointer that we pass to construct must point to space allocated by the same allocator object. The pointer that we pass to placement new need not point to memory allocated by operator new. Indeed, as we'll see in § 19.6 (p. 851), the pointer passed to a placement new expression need not even refer to dynamic memory.

Explicit Destructor Invocation

Just as placement new is analogous to using allocate, an explicit call to a destructor is analogous to calling destroy. We call a destructor the same way we call any other member function on an object or through a pointer or reference to an object:

```
string *sp = new string("a value"); // allocate and initialize a string
```

Here we invoke a destructor directly. The arrow operator dereferences the pointer sp to obtain the object to which sp points. We then call the destructor, which is the name of the type preceded by a tilde (~).

Like calling destroy, calling a destructor cleans up the given object but does not free the space in which that object resides. We can reuse the space if desired.

Note

Calling a destructor destroys an object but does not free the memory.

19.2. Run-Time Type Identification

Run-time type identification (RTTI) is provided through two operators:

- The typeid operator, which returns the type of a given expression
- The dynamic_cast operator, which safely converts a pointer or reference to a base type into a pointer or reference to a derived type

When applied to pointers or references to types that have virtual functions, these operators use the dynamic type (§ 15.2.3, p. 601) of the object to which the pointer or reference is bound.

These operators are useful when we have a derived operation that we want to perform through a pointer or reference to a base-class object and it is not possible to make that operation a virtual function. Ordinarily, we should use virtual functions if we can. When the operation is virtual, the compiler automatically selects the right function according to the dynamic type of the object.

However, it is not always possible to define a virtual. If we cannot use a virtual, we can use one of the RTTI operators. On the other hand, using these operators is more error-prone than using virtual member functions: The programmer must know to which type the object should be cast and must check that the cast was performed successfully.

Warning

RTTI should be used with caution. When possible, it is better to define a virtual function rather than to take over managing the types directly.

19.2.1. The dynamic_cast Operator

A **dynamic_cast** has the following form:

```
dynamic_cast<type*>(e)
dynamic_cast<type&>(e)
dynamic_cast<type&</pre>
```

where type must be a class type and (ordinarily) names a class that has virtual functions. In the first case, e must be a valid pointer (§ 2.3.2, p. 52); in the second, e must be an Ivalue; and in the third, e must not be an Ivalue.

In all cases, the type of e must be either a class type that is publicly derived from the target type, a public base class of the target type, or the same as the target type. If e has one of these types, then the cast will succeed. Otherwise, the cast fails. If a dynamic_cast to a pointer type fails, the result is 0. If a dynamic_cast to a reference type fails, the operator throws an exception of type bad_cast.

Pointer-Type dynamic_casts

As a simple example, assume that Base is a class with at least one virtual function and that class Derived is publicly derived from Base. If we have a pointer to Base named bp, we can cast it, at run time, to a pointer to Derived as follows:

Click here to view code image

```
if (Derived *dp = dynamic_cast<Derived*>(bp))
{
    // use the Derived object to which dp points
} else { // bp points at a Base object
    // use the Base object to which bp points
}
```

If bp points to a Derived object, then the cast will initialize dp to point to the Derived object to which bp points. In this case, it is safe for the code inside the if to use Derived operations. Otherwise, the result of the cast is 0. If dp is 0, the condition in the if fails. In this case, the else clause does processing appropriate to Base instead.

Note

We can do a dynamic_cast on a null pointer; the result is a null pointer of the requested type.

It is worth noting that we defined dp inside the condition. By defining the variable in a condition, we do the cast and corresponding check as a single operation. Moreover, the pointer dp is not accessible outside the if. If the cast fails, then the unbound pointer is not available for use in subsequent code where we might forget to check

whether the cast succeeded.

Best Practices

Performing a dynamic_cast in a condition ensures that the cast and test of its result are done in a single expression.

Reference-Type dynamic_casts

A dynamic_cast to a reference type differs from a dynamic_cast to a pointer type in how it signals that an error occurred. Because there is no such thing as a null reference, it is not possible to use the same error-reporting strategy for references that is used for pointers. When a cast to a reference type fails, the cast throws a std::bad_cast exception, which is defined in the typeinfo library header.

We can rewrite the previous example to use references as follows:

Click here to view code image

19.2.2. The typeid Operator

The second operator provided for RTTI is the **typeid operator**. The typeid operator allows a program to ask of an expression: What type is your object?

Exercises Section 19.2.1

Exercise 19.3: Given the following class hierarchy in which each class defines a public default constructor and virtual destructor:

```
class A { /* ... */ };
class B : public A { /* ... */ };
class C : public B { /* ... */ };
class D : public B, public A { /* ... */ };
```

which, if any, of the following dynamic_casts fail?

```
(a) A *pa = new C;
    B *pb = dynamic_cast< B* >(pa);
(b) B *pb = new B;
    C *pc = dynamic_cast< C* >(pb);
(c) A *pa = new D;
    B *pb = dynamic_cast< B* >(pa);
```

Exercise 19.4: Using the classes defined in the first exercise, rewrite the following code to convert the expression *pa to the type C&:

Click here to view code image

```
if (C *pc = dynamic_cast< C* >(pa))
    // use C's members
} else {
    // use A's members
}
```

Exercise 19.5: When should you use a dynamic_cast instead of a virtual function?

A typeid expression has the form typeid(e) where e is any expression or a type name. The result of a typeid operation is a reference to a const object of a library type named type_info, or a type publicly derived from type_info. § 19.2.4 (p. 831) covers this type in more detail. The type_info class is defined in the typeinfo header.

The typeid operator can be used with expressions of any type. As usual, top-level const (§ 2.4.3, p. 63) is ignored, and if the expression is a reference, typeid returns the type to which the reference refers. When applied to an array or function, however, the standard conversion to pointer (§ 4.11.2, p. 161) is not done. That is, if we take typeid(a) and a is an array, the result describes an array type, not a pointer type.

When the operand is not of class type or is a class without virtual functions, then the typeid operator indicates the static type of the operand. When the operand is an Ivalue of a class type that defines at least one virtual function, then the type is evaluated at run time.

Using the typeid Operator

Ordinarily, we use typeid to compare the types of two expressions or to compare the type of an expression to a specified type:

```
Derived *dp = new Derived;
```

```
Base *bp = dp; // both pointers point to a Derived object
// compare the type of two objects at run time
if (typeid(*bp) == typeid(*dp)) {
     // bp and dp point to objects of the same type
// test whether the run-time type is a specific type
if (typeid(*bp) == typeid(Derived)) {
     // bp actually points to a Derived
```

In the first if, we compare the dynamic types of the objects to which be and de point. If both point to the same type, then the condition succeeds. Similarly, the second if succeeds if bp currently points to a Derived object.

Note that the operands to the typeid are objects—we used *bp, not bp:

Click here to view code image

```
// test always fails: the type of bp is pointer to Base
if (typeid(bp) == typeid(Derived)) {
     // code never executed
```

This condition compares the type Base* to type Derived. Although the pointer points at an object of class type that has virtual functions, the pointer itself is not a class-type object. The type Base* can be, and is, evaluated at compile time. That type is unequal to Derived, so the condition will always fail regardless of the type of the object to which bp points.

Warning

The typeid of a pointer (as opposed to the object to which the pointer points) returns the static, compile-time type of the pointer.

Whether typeid requires a run-time check determines whether the expression is evaluated. The compiler evaluates the expression only if the type has virtual functions. If the type has no virtuals, then typeid returns the static type of the expression; the compiler knows the static type without evaluating the expression.

If the dynamic type of the expression might differ from the static type, then the expression must be evaluated (at run time) to determine the resulting type. The distinction matters when we evaluate typeid(*p). If p is a pointer to a type that does not have virtual functions, then p does not need to be a valid pointer. Otherwise, *p is evaluated at run time, in which case p must be a valid pointer. If p is a null pointer, then typeid(*p) throws a bad_typeid exception.

19.2.3. Using RTTI

As an example of when RTTI might be useful, consider a class hierarchy for which we'd like to implement the equality operator (§ 14.3.1, p. 561). Two objects are equal if they have the same type and same value for a given set of their data members. Each derived type may add its own data, which we will want to include when we test for equality.

Exercises Section 19.2.2

Exercise 19.6: Write an expression to dynamically cast a pointer to a Query_base to a pointer to an AndQuery (§ 15.9.1, p. 636). Test the cast by using objects of AndQuery and of another query type. Print a statement indicating whether the cast works and be sure that the output matches your expectations.

Exercise 19.7: Write the same cast, but cast a <code>Query_base</code> object to a reference to <code>AndQuery</code>. Repeat the test to ensure that your cast works correctly.

Exercise 19.8: Write a typeid expression to see whether two Query_base pointers point to the same type. Now check whether that type is an AndQuery.

We might think we could solve this problem by defining a set of virtual functions that would perform the equality test at each level in the hierarchy. Given those virtuals, we would define a single equality operator that operates on references to the base type. That operator could delegate its work to a virtual equal operation that would do the real work.

Unfortunately, this strategy doesn't quite work. Virtual functions must have the same parameter type(s) in both the base and derived classes (§ 15.3, p. 605). If we wanted to define a virtual equal function, that function must have a parameter that is a reference to the base class. If the parameter is a reference to base, the equal function could use only members from the base class. equal would have no way to compare members that are in the derived class but not in the base.

We can write our equality operation by realizing that the equality operator ought to return false if we attempt to compare objects of differing type. For example, if we try to compare a object of the base-class type with an object of a derived type, the == operator should return false.

Given this observation, we can now see that we can use RTTI to solve our problem. We'll define an equality operator whose parameters are references to the base-class type. The equality operator will use typeid to verify that the operands have the same type. If the operands differ, the == will return false. Otherwise, it will call a virtual equal function. Each class will define equal to compare the data elements of its own type. These operators will take a Base& parameter but will cast the operand to its own type before doing the comparison.

The Class Hierarchy

To make the concept a bit more concrete, we'll define the following classes:

Click here to view code image

```
class Base {
    friend bool operator==(const Base&, const Base&);
public:
    // interface members for Base
protected:
    virtual bool equal(const Base&) const;
    // data and other implementation members of Base
};
class Derived: public Base {
public:
    // other interface members for Derived
protected:
    bool equal(const Base&) const;
    // data and other implementation members of Derived
};
```

A Type-Sensitive Equality Operator

Next let's look at how we might define the overall equality operator:

Click here to view code image

```
bool operator==(const Base &lhs, const Base &rhs)
{
    // returns false if typeids are different; otherwise makes a virtual call to equal
    return typeid(lhs) == typeid(rhs) && lhs.equal(rhs);
}
```

This operator returns false if the operands are different types. If they are the same type, then it delegates the real work of comparing the operands to the (virtual) equal function. If the operands are Base objects, then Base::equal will be called. If they are Derived objects, Derived::equal is called.

The Virtual equal Functions

Each class in the hierarchy must define its own version of equal. All of the functions in the derived classes will start the same way: They'll cast their argument to the type of the class itself:

```
bool Derived::equal(const Base &rhs) const
```

```
{
    // we know the types are equal, so the cast won't throw
    auto r = dynamic_cast<const Derived&>(rhs);
    // do the work to compare two Derived objects and return the result
}
```

The cast should always succeed—after all, the function is called from the equality operator only after testing that the two operands are the same type. However, the cast is necessary so that the function can access the derived members of the right-hand operand.

The Base-Class equal Function

This operation is a bit simpler than the others:

Click here to view code image

```
bool Base::equal(const Base &rhs) const
{
    // do whatever is required to compare to Base objects
}
```

There is no need to cast the parameter before using it. Both *this and the parameter are Base objects, so all the operations available for this object are also defined for the parameter type.

19.2.4. The type_info Class

The exact definition of the **type_info** class varies by compiler. However, the standard guarantees that the class will be defined in the typeinfo header and that the class will provide at least the operations listed in Table 19.1.

Table 19.1. Operations on type_info

t1 == t2	Returns true if the type_info objects t1 and t2 refer to the same type, false otherwise.
t1 != t2	Returns true if the type_info objects t1 and t2 refer to different types, false otherwise.
t.name()	Returns a C-style character string that is a printable version of the type name. Type names are generated in a system-dependent way.
t1.before(t2)	Returns a bool that indicates whether t1 comes before t2. The ordering imposed by before is compiler dependent.

The class also provides a public virtual destructor, because it is intended to serve as a base class. When a compiler wants to provide additional type information, it normally does so in a class derived from type_info.

There is no type info default constructor, and the copy and move constructors and the assignment operators are all defined as deleted (§ 13.1.6, p. 507). Therefore, we cannot define, copy, or assign objects of type type info. The only way to create a type_info object is through the typeid operator.

The name member function returns a C-style character string for the name of the type represented by the type info object. The value used for a given type depends on the compiler and in particular is not required to match the type names as used in a program. The only guarantee we have about the return from name is that it returns a unique string for each type. For example:

Click here to view code image

```
int arr[10];
Derived d;
Base *p = \&d;
cout << typeid(42).name() << ",</pre>
     << typeid(arr).name() << ",</pre>
     << typeid(Sales_data).name() << ",
     << typeid(std::string).name() << ",
     << typeid(p).name() << ",
     << typeid(*p).name() << endl;</pre>
```

This program, when executed on our machine, generates the following output:

Click here to view code image

i, A10_i, 10Sales_data, Ss, P4Base, 7Derived

The type_info class varies by compiler. Some compilers provide additional member functions that provide additional information about types used in a program. You should consult the reference manual for your compiler to understand the exact type info support provided.

Exercises Section 19.2.4

Exercise 19.9: Write a program similar to the last one in this section to print the names your compiler uses for common type names. If your compiler gives output similar to ours, write a function that will translate those strings to more human-friendly form.

Exercise 19.10: Given the following class hierarchy in which each class defines a public default constructor and virtual destructor, which type name do the following statements print?

```
class A { /* ... */ };
class B : public A { /* ... */ };
class C : public B { /* ... */ };

(a) A *pa = new C;
    cout << typeid(pa).name() << endl;
(b) C cobj;
    A& ra = cobj;
    cout << typeid(&ra).name() << endl;
(c) B *px = new B;
    A& ra = *px;
    cout << typeid(ra).name() << endl;</pre>
```

19.3. Enumerations

Enumerations let us group together sets of integral constants. Like classes, each enumeration defines a new type. Enumerations are literal types (§ 7.5.6, p. 299).

C++ has two kinds of enumerations: scoped and unscoped. The new standard introduced scoped enumerations. We define a scoped enumeration using the keywords enum class (or, equivalently, enum struct), followed by the enumeration name and a comma-separated list of enumerators enclosed in curly braces. A semicolon follows the close curly:

Click here to view code image

```
enum class open_modes {input, output, append};
```

Here we defined an enumeration type named open_modes that has three enumerators: input, output, and append.

We define an **unscoped enumeration** by omitting the class (or struct) keyword. The enumeration name is optional in an unscoped enum:

Click here to view code image

```
enum color {red, yellow, green};  // unscoped enumeration
// unnamed, unscoped enum
enum {floatPrec = 6, doublePrec = 10, double_doublePrec = 10};
```

If the enum is unnamed, we may define objects of that type only as part of the enum definition. As with a class definition, we can provide a comma-separated list of declarators between the close curly and the semicolon that ends the enum definition (§ 2.6.1, p. 73).

Enumerators

The names of the enumerators in a scoped enumeration follow normal scoping rules and are inaccessible outside the scope of the enumeration. The enumerator names in an unscoped enumeration are placed into the same scope as the enumeration itself:

Click here to view code image

By default, enumerator values start at 0 and each enumerator has a value 1 greater than the preceding one. However, we can also supply initializers for one or more enumerators:

Click here to view code image

```
enum class intTypes {
    charTyp = 8, shortTyp = 16, intTyp = 16,
    longTyp = 32, long_longTyp = 64
};
```

As we see with the enumerators for intTyp and shortTyp, an enumerator value need not be unique. When we omit an initializer, the enumerator has a value 1 greater than the preceding enumerator.

Enumerators are const and, if initialized, their initializers must be constant expressions (§ 2.4.4, p. 65). Consequently, each enumerator is itself a constant expression. Because the enumerators are constant expressions, we can use them where a constant expression is required. For example, we can define constexpr variables of enumeration type:

Click here to view code image

```
constexpr intTypes charbits = intTypes::charTyp;
```

Similarly, we can use an enum as the expression in a switch statement and use the value of its enumerators as the case labels (§ 5.3.2, p. 178). For the same reason, we can also use an enumeration type as a nontype template parameter (§ 16.1.1, p. 654). and can initialize class static data members of enumeration type inside the class definition (§ 7.6, p. 302).

Like Classes, Enumerations Define New Types

So long as the enum is named, we can define and initialize objects of that type. An enum object may be initialized or assigned only by one of its enumerators or by another object of the same enum type:

Click here to view code image

Objects or enumerators of an unscoped enumeration type are automatically converted to an integral type. As a result, they can be used where an integral value is required:

Click here to view code image

Specifying the Size of an enum

Although each enum defines a unique type, it is represented by one of the built-in integral types. Under the new standard, we may specify that type by following the enum name with a colon and the name of the type we want to use:

Click here to view code image

```
enum intValues : unsigned long long {
    charTyp = 255, shortTyp = 65535, intTyp = 65535,
    longTyp = 4294967295UL,
    long_longTyp = 18446744073709551615ULL
};
```

If we do not specify the underlying type, then by default scoped enums have int as the underlying type. There is no default for unscoped enums; all we know is that the underlying type is large enough to hold the enumerator values. When the underlying type is specified (including implicitly specified for a scoped enum), it is an error for an enumerator to have a value that is too large to fit in that type.

Being able to specify the underlying type of an enum lets us control the type used across different implementations. We can be confident that our program compiled under one implementation will generate the same code when we compile it on another.

Forward Declarations for Enumerations

Under the new standard, we can forward declare an enum. An enum forward declaration must specify (implicitly or explicitly) the underlying size of the enum:

Click here to view code image

```
// forward declaration of unscoped enum named intValues
enum intValues : unsigned long long; // unscoped, must specify a type
enum class open_modes; // scoped enums can use int by default
```

Because there is no default size for an unscoped <code>enum</code>, every declaration must include the size of that <code>enum</code>. We can declare a scoped <code>enum</code> without specifying a size, in which case the size is implicitly defined as <code>int</code>.

As with any declaration, all the declarations and the definition of a given enum must match one another. In the case of enums, this requirement means that the size of the enum must be the same across all declarations and the enum definition. Moreover, we cannot declare a name as an unscoped enum in one context and redeclare it as a scoped enum later:

Click here to view code image

```
// error: declarations and definition must agree whether the enum is scoped or unscoped
enum class intValues;
enum intValues; // error: intValues previously declared as scoped enum
enum intValues : long; // error: intValues previously declared as int
```

Parameter Matching and Enumerations

Because an object of enum type may be initialized only by another object of that enum type or by one of its enumerators (§ 19.3, p. 833), an integral value that happens to have the same value as an enumerator cannot be used to call a function expecting an enum argument:

Click here to view code image

Although we cannot pass an integral value to an enum parameter, we can pass an

object or enumerator of an unscoped enumeration to a parameter of integral type. When we do so, the enum value promotes to int or to a larger integral type. The actual promotion type depends on the underlying type of the enumeration:

Click here to view code image

```
void newf(unsigned char);
void newf(int);
unsigned char uc = VIRTUAL;
newf(VIRTUAL); // calls newf(int)
newf(uc); // calls newf(unsigned char)
```

The enum Tokens has only two enumerators, the larger of which has the value 129. That value can be represented by the type unsigned char, and many compilers will use unsigned char as the underlying type for Tokens. Regardless of its underlying type, objects and the enumerators of Tokens are promoted to int. Enumerators and values of an enum type are not promoted to unsigned char, even if the values of the enumerators would fit.

19.4. Pointer to Class Member

A **pointer to member** is a pointer that can point to a nonstatic member of a class. Normally a pointer points to an object, but a pointer to member identifies a member of a class, not an object of that class. static class members are not part of any object, so no special syntax is needed to point to a static member. Pointers to static members are ordinary pointers.

The type of a pointer to member embodies both the type of a class and the type of a member of that class. We initialize such pointers to point to a specific member of a class without identifying an object to which that member belongs. When we use a pointer to member, we supply the object whose member we wish to use.

To explain pointers to members, we'll use a version of the Screen class from § 7.3.1 (p. 271):

Click here to view code image

```
class Screen {
public:
    typedef std::string::size_type pos;
    char get_cursor() const { return contents[cursor]; }
    char get() const;
    char get(pos ht, pos wd) const;

private:
    std::string contents;
    pos cursor;
    pos height, width;
};
```

19.4.1. Pointers to Data Members

As with any pointer, we declare a pointer to member using a * to indicate that the name we're declaring is a pointer. Unlike ordinary pointers, a pointer to member also incorporates the class that contains the member. Hence, we must precede the * with classname: to indicate that the pointer we are defining can point to a member of classname. For example:

Click here to view code image

```
// pdata can point to a string member of a const (or non const) Screen object const string Screen: *pdata;
```

declares that pdata is a "pointer to a member of class Screen that has type const string." The data members in a const object are themselves const. By making our pointer a pointer to const string member, we say that we can use pdata to point to a member of any Screen object, const or not. In exchange we can use pdata to read, but not write to, the member to which it points.

When we initialize (or assign to) a pointer to member, we say to which member it points. For example, we can make pdata point to the contents member of an unspecified Screen object as follows:

```
pdata = &Screen::contents;
```

Here, we apply the address-of operator not to an object in memory but to a member of the class Screen.

Of course, under the new standard, the easiest way to declare a pointer to member is to use auto or decltype:

```
auto pdata = &Screen::contents;
```

Using a Pointer to Data Member

It is essential to understand that when we initialize or assign a pointer to member, that pointer does not yet point to any data. It identifies a specific member but not the object that contains that member. We supply the object when we dereference the pointer to member.

Analogous to the member access operators, . and ->, there are two pointer-to-member access operators, .* and ->*, that let us supply an object and dereference the pointer to fetch a member of that object:

```
Screen myScreen, *pScreen = &myScreen;
// .*dereferences pdata to fetch the contents member from the object myScreen
auto s = myScreen.*pdata;
// ->*dereferences pdata to fetch contents from the object to which pScreen points
s = pScreen->*pdata;
```

Conceptually, these operators perform two actions: They dereference the pointer to member to get the member that we want; then, like the member access operators, they fetch that member from an object (.*) or through a pointer (->*).

A Function Returning a Pointer to Data Member

Normal access controls apply to pointers to members. For example, the contents member of Screen is private. As a result, the use of pdata above must have been inside a member or friend of class Screen or it would be an error.

Because data members are typically private, we normally can't get a pointer to data member directly. Instead, if a class like Screen wanted to allow access to its contents member, it would define a function to return a pointer to that member:

Click here to view code image

Here we've added a static member to class Screen that returns a pointer to the contents member of a Screen. The return type of this function is the same type as our original pdata pointer. Reading the return type from right to left, we see that data returns a pointer to a member of class Screen that is a string that is const. The body of the function applies the address-of operator to the contents member, so the function returns a pointer to the contents member of Screen.

When we call data, we get a pointer to member:

Click here to view code image

```
// data() returns a pointer to the contents member of class Screen
const string Screen::*pdata = Screen::data();
```

As before, pdata points to a member of class Screen but not to actual data. To use pdata, we must bind it to an object of type Screen

Click here to view code image

```
// fetch the contents of the object named myScreen
auto s = myScreen.*pdata;
```

Exercises Section 19.4.1

Exercise 19.11: What is the difference between an ordinary data pointer and a pointer to a data member?

Exercise 19.12: Define a pointer to member that can point to the cursor member of class Screen. Fetch the value of Screen::cursor through that pointer.

Exercise 19.13: Define the type that can represent a pointer to the bookNo member of the Sales_data class.

19.4.2. Pointers to Member Functions

We can also define a pointer that can point to a member function of a class. As with pointers to data members, the easiest way to form a pointer to member function is to use auto to deduce the type for us:

Click here to view code image

```
// pmf is a pointer that can point to a Screen member function that is const
// that returns a char and takes no arguments
auto pmf = &Screen::get_cursor;
```

Like a pointer to data member, a pointer to a function member is declared using classname: :*. Like any other function pointer (§ 6.7, p. 247), a pointer to member function specifies the return type and parameter list of the type of function to which this pointer can point. If the member function is a const member (§ 7.1.2, p. 258) or a reference member (§ 13.6.3, p. 546), we must include the const or reference qualifier as well.

As with normal function pointers, if the member is overloaded, we must distinguish which function we want by declaring the type explicitly (§ 6.7, p. 248). For example, we can declare a pointer to the two-parameter version of get as

Click here to view code image

```
char (Screen::*pmf2)(Screen::pos, Screen::pos) const;
pmf2 = &Screen::get;
```

The parentheses around Screen::* in this declaration are essential due to precedence. Without the parentheses, the compiler treats the following as an (invalid) function declaration:

Click here to view code image

```
// error: nonmember function p cannot have a const qualifier
char Screen::*p(Screen::pos, Screen::pos) const;
```

This declaration tries to define an ordinary function named p that returns a pointer to a member of class Screen that has type char. Because it declares an ordinary function, the declaration can't be followed by a const qualifier.

Unlike ordinary function pointers, there is no automatic conversion between a

member function and a pointer to that member:

Click here to view code image

```
// pmf points to a Screen member that takes no arguments and returns char
pmf = &Screen::get; // must explicitly use the address-of operator
pmf = Screen::get; // error: no conversion to pointer for member functions
```

Using a Pointer to Member Function

As when we use a pointer to a data member, we use the .* or ->* operators to call a member function through a pointer to member:

Click here to view code image

```
Screen myScreen, *pScreen = &myScreen;
// call the function to which pmf points on the object to which pScreen points
char c1 = (pScreen->*pmf)();
// passes the arguments 0, 0 to the two-parameter version of get on the object
myScreen
char c2 = (myScreen.*pmf2)(0, 0);
```

The calls (myScreen->*pmf)() and (pScreen.*pmf2)(0,0) require the parentheses because the precedence of the call operator is higher than the precedence of the pointer to member operators.

Without the parentheses,

```
myScreen.*pmf()
```

would be interpreted to mean

```
myScreen.*(pmf())
```

This code says to call the function named pmf and use its return value as the operand of the pointer-to-member operator (.*). However, pmf is not a function, so this code is in error.

Note

Because of the relative precedence of the call operator, declarations of pointers to member functions and calls through such pointers must use parentheses: (C::*p)(parms) and (obj.*p)(args).

Using Type Aliases for Member Pointers

Type aliases or typedefs (§ 2.5.1, p. 67) make pointers to members considerably

easier to read. For example, the following type alias defines Action as an alternative name for the type of the two-parameter version of get:

Click here to view code image

```
// Action is a type that can point to a member function of Screen
// that returns a char and takes two pos arguments
using Action =
char (Screen::*)(Screen::pos, Screen::pos) const;
```

Action is another name for the type "pointer to a const member function of class Screen taking two parameters of type pos and returning char." Using this alias, we can simplify the definition of a pointer to get as follows:

Click here to view code image

```
Action get = &Screen::get; // get points to the get member of Screen
```

As with any other function pointer, we can use a pointer-to-member function type as the return type or as a parameter type in a function. Like any other parameter, a pointer-to-member parameter can have a default argument:

Click here to view code image

```
// action takes a reference to a Screen and a pointer to a Screen member function
Screen& action(Screen&, Action = &Screen::get);
```

action is a function taking two parameters, which are a reference to a Screen object and a pointer to a member function of class Screen that takes two pos parameters and returns a char. We can call action by passing it either a pointer or the address of an appropriate member function in Screen:

Click here to view code image

```
Screen myScreen;
// equivalent calls:
action(myScreen); // uses the default argument
action(myScreen, get); // uses the variable get that we previously defined
action(myScreen, &Screen::get); // passes the address explicitly
```

Note

Type aliases make code that uses pointers to members much easier to read and write.

Pointer-to-Member Function Tables

One common use for function pointers and for pointers to member functions is to

store them in a function table (§ 14.8.3, p. 577). For a class that has several members of the same type, such a table can be used to select one from the set of these members. Let's assume that our Screen class is extended to contain several member functions, each of which moves the cursor in a particular direction:

Click here to view code image

```
class Screen {
public:
    // other interface and implementation members as before
    Screen& home();    // cursor movement functions
    Screen& forward();
    Screen& back();
    Screen& up();
    Screen& down();
};
```

Each of these new functions takes no parameters and returns a reference to the Screen on which it was invoked.

We might want to define a move function that can call any one of these functions and perform the indicated action. To support this new function, we'll add a static member to Screen that will be an array of pointers to the cursor movement functions:

Click here to view code image

```
class Screen {
public:
    // other interface and implementation members as before
    // Action is a pointer that can be assigned any of the cursor movement members
    using Action = Screen& (Screen::*)();
    // specify which direction to move; enum see § 19.3 (p. 832)
    enum Directions { HOME, FORWARD, BACK, UP, DOWN };
    Screen& move(Directions);
private:
    static Action Menu[];    // function table
};
```

The array named Menu will hold pointers to each of the cursor movement functions. Those functions will be stored at the offsets corresponding to the enumerators in Directions. The move function takes an enumerator and calls the appropriate function:

```
Screen& Screen::move(Directions cm)
{
    // run the element indexed by cm on this object
    return (this->*Menu[cm])(); // Menu[cm] points to a member
function
```

}

The call inside move is evaluated as follows: The Menu element indexed by cm is fetched. That element is a pointer to a member function of the Screen class. We call the member function to which that element points on behalf of the object to which this points.

When we call move, we pass it an enumerator that indicates which direction to move the cursor:

Click here to view code image

```
Screen myScreen;
myScreen.move(Screen::HOME); // invokes myScreen.home
myScreen.move(Screen::DOWN); // invokes myScreen.down
```

What's left is to define and initialize the table itself:

Exercises Section 19.4.2

Exercise 19.14: Is the following code legal? If so, what does it do? If not, why?

Click here to view code image

```
auto pmf = &Screen::get_cursor;
pmf = &Screen::get;
```

Exercise 19.15: What is the difference between an ordinary function pointer and a pointer to a member function?

Exercise 19.16: Write a type alias that is a synonym for a pointer that can point to the avg_price member of Sales_data.

Exercise 19.17: Define a type alias for each distinct Screen member function type.

19.4.3. Using Member Functions as Callable Objects

As we've seen, to make a call through a pointer to member function, we must use the .* or ->* operators to bind the pointer to a specific object. As a result, unlike ordinary function pointers, a pointer to member is *not* a callable object; these pointers

do not support the function-call operator (§ 10.3.2, p. 388).

Because a pointer to member is not a callable object, we cannot directly pass a pointer to a member function to an algorithm. As an example, if we wanted to find the first empty string in a vector of strings, the obvious call won't work:

Click here to view code image

```
auto fp = &string::empty;  // fp points to the string empty function
// error: must use .* or ->* to call a pointer to member
find_if(svec.begin(), svec.end(), fp);
```

The find_if algorithm expects a callable object, but we've supplied fp, which is a pointer to a member function. This call won't compile, because the code inside find_if executes a statement something like

Click here to view code image

```
// check whether the given predicate applied to the current element yields true if (fp(*it)) // error: must use ->* to call through a pointer to member
```

which attempts to call the object it was passed.

Using function to Generate a Callable

One way to obtain a callable from a pointer to member function is by using the library function template (§ 14.8.3, p. 577):

Click here to view code image

```
function<bool (const string&)> fcn = &string::empty;
find_if(svec.begin(), svec.end(), fcn);
```

Here we tell function that empty is a function that can be called with a string and returns a bool. Ordinarily, the object on which a member function executes is passed to the implicit this parameter. When we want to use function to generate a callable for a member function, we have to "translate" the code to make that implicit parameter explicit.

When a function object holds a pointer to a member function, the function class knows that it must use the appropriate pointer-to-member operator to make the call. That is, we can imagine that find_if will have code something like

Click here to view code image

```
// assuming it is the iterator inside find_if, so *it is an object in the given range if (fcn(*it)) // assuming fcn is the name of the callable inside find if
```

which function will execute using the proper pointer-to-member operator. In essence, the function class will transform this call into something like

```
// assuming it is the iterator inside find_if, so *it is an object in the given range if (((*it).*p)()) // assuming p is the pointer to member function inside fcn
```

When we define a function object, we must specify the function type that is the signature of the callable objects that object can represent. When the callable is a member function, the signature's first parameter must represent the (normally implicit) object on which the member will be run. The signature we give to function must specify whether the object will be passed as a pointer or a reference.

When we defined fcn, we knew that we wanted to call find_if on a sequence of string objects. Hence, we asked function to generate a callable that took string objects. Had our vector held pointers to string, we would have told function to expect a pointer:

Click here to view code image

```
vector<string*> pvec;
function<bool (const string*)> fp = &string::empty;
// fp takes a pointer to string and uses the ->* to call empty
find_if(pvec.begin(), pvec.end(), fp);
```

Using mem fn to Generate a Callable

To use function, we must supply the call signature of the member we want to call. We can, instead, let the compiler deduce the member's type by using another library facility, mem_fn, which, like function, is defined in the functional header. Like function, mem_fn generates a callable object from a pointer to member. Unlike function, mem_fn will deduce the type of the callable from the type of the pointer to member:

Click here to view code image

```
find_if(svec.begin(), svec.end(), mem_fn(&string::empty));
```

Here we used mem_fn(&string::empty) to generate a callable object that takes a string argument and returns a bool.

The callable generated by mem_fn can be called on either an object or a pointer:

Click here to view code image

```
auto f = mem_fn(&string::empty); // f takes a string or a string*
f(*svec.begin()); // ok: passes a string object; f uses .* to call empty
f(&svec[0]); // ok: passes a pointer to string; f uses .-> to call empty
```

Effectively, we can think of mem_fn as if it generates a callable with an overloaded function call operator—one that takes a string* and the other a string&.

Using bind to Generate a Callable

For completeness, we can also use bind (§ 10.3.4, p. 397) to generate a callable from a member function:

Click here to view code image

As with function, when we use bind, we must make explicit the member function's normally implicit parameter that represents the object on which the member function will operate. Like mem_fn, the first argument to the callable generated by bind can be either a pointer or a reference to a string:

Click here to view code image

```
auto f = bind(&string::empty, _1);
f(*svec.begin()); // ok: argument is a string f will use .* to call empty
f(&svec[0]); // ok: argument is a pointer to string f will use .-> to call empty
```

19.5. Nested Classes

A class can be defined within another class. Such a class is a **nested class**, also referred to as a **nested type**. Nested classes are most often used to define implementation classes, such as the QueryResult class we used in our text query example (§ 12.3, p. 484).

Exercises Section 19.4.3

Exercise 19.18: Write a function that uses count_if to count how many empty strings there are in a given vector.

Exercise 19.19: Write a function that takes a vector<Sales_data> and finds the first element whose average price is greater than some given amount.

Nested classes are independent classes and are largely unrelated to their enclosing class. In particular, objects of the enclosing and nested classes are independent from each other. An object of the nested type does not have members defined by the enclosing class. Similarly, an object of the enclosing class does not have members defined by the nested class.

The name of a nested class is visible within its enclosing class scope but not outside the class. Like any other nested name, the name of a nested class will not collide with the use of that name in another scope.

A nested class can have the same kinds of members as a nonnested class. Just like any other class, a nested class controls access to its own members using access specifiers. The enclosing class has no special access to the members of a nested class, and the nested class has no special access to members of its enclosing class.

A nested class defines a type member in its enclosing class. As with any other member, the enclosing class determines access to this type. A nested class defined in the public part of the enclosing class defines a type that may be used anywhere. A nested class defined in the protected section defines a type that is accessible only by the enclosing class, its friends, and its derived classes. A private nested class defines a type that is accessible only to the members and friends of the enclosing class.

Declaring a Nested Class

The TextQuery class from § 12.3.2 (p. 487) defined a companion class named QueryResult. The QueryResult class is tightly coupled to our TextQuery class. It would make little sense to use QueryResult for any other purpose than to represent the results of a query operation on a TextQuery object. To reflect this tight coupling, we'll make QueryResult a member of TextQuery.

Click here to view code image

```
class TextQuery {
public:
    class QueryResult; // nested class to be defined later
    // other members as in § 12.3.2 (p. 487)
};
```

We need to make only one change to our original TextQuery class—we declare our intention to define QueryResult as a nested class. Because QueryResult is a type member (§ 7.4.1, p. 284), we must declare QueryResult before we use it. In particular, we must declare QueryResult before we use it as the return type for the query member. The remaining members of our original class are unchanged.

Defining a Nested Class outside of the Enclosing Class

Inside TextQuery we declared QueryResult but did not define it. As with member functions, nested classes must be declared inside the class but can be defined either inside or outside the class.

When we define a nested class outside its enclosing class, we must qualify the name of the nested class by the name of its enclosing class:

```
// we're defining the QueryResult class that is a member of class TextQuery
class TextQuery::QueryResult {
     // in class scope, we don't have to qualify the name of the QueryResult
parameters
     friend std::ostream&
             print(std::ostream&, const QueryResult&);
public:
     // no need to define OueryResult::line no; a nested class can use a member
     // of its enclosing class without needing to qualify the member's name
     OueryResult(std::string,
                    std::shared ptr<std::set<line no>>,
                    std::shared_ptr<std::vector<std::string>>);
     // other members as in § 12.3.2 (p. 487)
};
```

The only change we made compared to our original class is that we no longer define a line no member in QueryResult. The members of QueryResult can access that name directly from TextOuery, so there is no need to define it again.

Warning

Until the actual definition of a nested class that is defined outside the class body is seen, that class is an incomplete type (§ 7.3.3, p. 278).

Defining the Members of a Nested Class

In this version, we did not define the QueryResult constructor inside the class body. To define the constructor, we must indicate that QueryResult is nested within the scope of TextQuery. We do so by qualifying the nested class name with the name of its enclosing class:

Click here to view code image

```
// defining the member named QueryResult for the class named QueryResult
// that is nested inside the class TextQuery
TextQuery::QueryResult::QueryResult(string s,
                   shared_ptr<set<line_no>> p,
                   shared_ptr<vector<string>> f):
         sought(s), lines(p), file(f) { }
```

Reading the name of the function from right to left, we see that we are defining the constructor for class QueryResult, which is nested in the scope of class TextQuery. The code itself just stores the given arguments in the data members and has no further work to do.

Nested-Class static Member Definitions

If QueryResult had declared a static member, its definition would appear outside the scope of the TextQuery. For example, assuming QueryResult had a static member, its definition would look something like

Click here to view code image

```
// defines an int static member of QueryResult
// which is a class nested inside TextQuery
int TextQuery::QueryResult::static_mem = 1024;
```

Name Lookup in Nested Class Scope

Normal rules apply for name lookup (§ 7.4.1, p. 283) inside a nested class. Of course, because a nested class is a nested scope, the nested class has additional enclosing class scopes to search. This nesting of scopes explains why we didn't define line_no inside the nested version of QueryResult. Our original QueryResult class defined this member so that its own members could avoid having to write TextQuery::line_no. Having nested the definition of our results class inside TextQuery, we no longer need this typedef. The nested QueryResult class can access line_no without specifying that line_no is defined in TextQuery.

As we've seen, a nested class is a type member of its enclosing class. Members of the enclosing class can use the name of a nested class the same way it can use any other type member. Because QueryResult is nested inside TextQuery, the query member of TextQuery can refer to the name QueryResult directly:

Click here to view code image

```
// return type must indicate that QueryResult is now a nested class
TextQuery::QueryResult
TextQuery::query(const string &sought) const
{
    // we'll return a pointer to this set if we don't find sought
    static shared_ptr<set<line_no>> nodata(new set<line_no>);
    // use find and not a subscript to avoid adding words to wm!
    auto loc = wm.find(sought);
    if (loc == wm.end())
        return QueryResult(sought, nodata, file); // not found
    else
        return QueryResult(sought, loc->second, file);
}
```

As usual, the return type is not yet in the scope of the class (§ 7.4, p. 282), so we start by noting that our function returns a TextQuery::QueryResult value. However, inside the body of the function, we can refer to QueryResult directly, as we do in the return statements.

The Nested and Enclosing Classes Are Independent

Although a nested class is defined in the scope of its enclosing class, it is important to understand that there is no connection between the objects of an enclosing class and objects of its nested classe(s). A nested-type object contains only the members defined inside the nested type. Similarly, an object of the enclosing class has only those members that are defined by the enclosing class. It does not contain the data members of any nested classes.

More concretely, the second return statement in TextQuery::query

Click here to view code image

```
return QueryResult(sought, loc->second, file);
```

uses data members of the TextQuery object on which query was run to initialize a QueryResult object. We have to use these members to construct the QueryResult object we return because a QueryResult object does not contain the members of its enclosing class.

Exercises Section 19.5

Exercise 19.20: Nest your QueryResult class inside TextQuery and rerun the programs you wrote to use TextQuery in § 12.3.2 (p. 490).

19.6. union: A Space-Saving Class

A union is a special kind of class. A union may have multiple data members, but at any point in time, only one of the members may have a value. When a value is assigned to one member of the union, all other members become undefined. The amount of storage allocated for a union is at least as much as is needed to contain its largest data member. Like any class, a union defines a new type.

Some, but not all, class features apply equally to unions. A union cannot have a member that is a reference, but it can have members of most other types, including, under the new standard, class types that have constructors or destructors. A union can specify protection labels to make members public, private, or protected. By default, like structs, members of a union are public.

A union may define member functions, including constructors and destructors. However, a union may not inherit from another class, nor may a union be used as a base class. As a result, a union may not have virtual functions.

Defining a union

unions offer a convenient way to represent a set of mutually exclusive values of different types. As an example, we might have a process that handles different kinds

of numeric or character data. That process might define a union to hold these values:

Click here to view code image

```
// objects of type Token have a single member, which could be of any of the listed types
union Token {
// members are public by default
    char cval;
    int ival;
    double dval;
};
```

A union is defined starting with the keyword union, followed by an (optional) name for the union and a set of member declarations enclosed in curly braces. This code defines a union named Token that can hold a value that is either a char, an int, or a double.

Using a union Type

The name of a union is a type name. Like the built-in types, by default unions are uninitialized. We can explicitly initialize a union in the same way that we can explicitly initialize aggregate classes (§ 7.5.5, p. 298) by enclosing the initializer in a pair of curly braces:

Click here to view code image

```
Token first_token = {'a'}; // initializes the cval member

Token last_token; // uninitialized Token object

Token *pt = new Token; // pointer to an uninitialized Token object
```

If an initializer is present, it is used to initialize the first member. Hence, the initialization of first_token gives a value to its cval member.

The members of an object of union type are accessed using the normal member access operators:

```
last_token.cval = 'z';
pt->ival = 42;
```

Assigning a value to a data member of a union object makes the other data members undefined. As a result, when we use a union, we must always know what type of value is currently stored in the union. Depending on the types of the members, retrieving or assigning to the value stored in the union through the wrong data member can lead to a crash or other incorrect program behavior.

Anonymous unions

An anonymous union is an unnamed union that does not include any declarations

between the close curly that ends its body and the semicolon that ends the union definition (§ 2.6.1, p. 73). When we define an anonymous union the compiler automatically creates an unnamed object of the newly defined union type:

Click here to view code image

The members of an anonymous union are directly accessible in the scope where the anonymous union is defined.

Note

An anonymous union cannot have private or protected members, nor can an anonymous union define member functions.

unions with Members of Class Type

Under earlier versions of C++, unions could not have members of a class type that defined its own constructors or copy-control members. Under the new standard, this restriction is lifted. However, unions with members that define their own constructors and/or copy-control members are more complicated to use than unions that have members of built-in type.

When a union has members of built-in type, we can use ordinary assignment to change the value that the union holds. Not so for unions that have members of nontrivial class types. When we switch the union's value to and from a member of class type, we must construct or destroy that member, respectively: When we switch the union to a member of class type, we must run a constructor for that member's type; when we switch from that member, we must run its destructor.

When a union has members of built-in type, the compiler will synthesize the memberwise versions of the default constructor or copy-control members. The same is not true for unions that have members of a class type that defines its own default constructor or one or more of the copy-control members. If a union member's type defines one of these members, the compiler synthesizes the corresponding member of the union as deleted (§ 13.1.6, p. 508).

For example, the string class defines all five copy-control members and the

default constructor. If a union contains a string and does not define its own default constructor or one of the copy-control members, then the compiler will synthesize that missing member as deleted. If a class has a union member that has a deleted copy-control member, then that corresponding copy-control operation(s) of the class itself will be deleted as well.

Using a Class to Manage union Members

Because of the complexities involved in constructing and destroying members of class type, unions with class-type members ordinarily are embedded inside another class. That way the class can manage the state transitions to and from the member of class type. As an example, we'll add a string member to our union. We'll define our union as an anonymous union and make it a member of a class named Token. The Token class will manage the union's members.

To keep track of what type of value the union holds, we usually define a separate object known as a **discriminant**. A discriminant lets us discriminate among the values that the union can hold. In order to keep the union and its discriminant in sync, we'll make the discriminant a member of Token as well. Our class will define a member of an enumeration type (§ 19.3, p. 832) to keep track of the state of its union member.

The only functions our class will define are the default constructor, the copy-control members, and a set of assignment operators that can assign a value of one of our union's types to the union member:

```
class Token {
public:
     // copy control needed because our class has a union with a string member
     // defining the move constructor and move-assignment operator is left as an
exercise
     Token(): tok(INT), ival{0} {
     Token(const Token &t): tok(t.tok) { copyUnion(t); }
     Token & operator = (const Token&);
     // if the union holds a string, we must destroy it; see § 19.1.2 (p. 824)
     ~Token() { if (tok == STR) sval.~string(); }
     // assignment operators to set the differing members of the union
     Token & operator = (const std::string&);
     Token & operator = (char);
     Token & operator = (int);
     Token & operator = (double);
private:
     enum {INT, CHAR, DBL, STR} tok; // discriminant
                                            // anonymous union
     union {
          char cval;
int ival;
```

```
double dval;
    std::string sval;
}; // each Token object has an unnamed member of this unnamed union type
    // check the discriminant and copy the union member as appropriate
    void copyUnion(const Token&);
};
```

Our class defines a nested, unnamed, unscoped enumeration (§ 19.3, p. 832) that we use as the type for the member named tok. We defined tok following the close curly and before the semicolon that ends the definition of the enum, which defines tok to have this unnamed enum type (§ 2.6.1, p. 73).

We'll use tok as our discriminant. When the union holds an int value, tok will have the value INT; if the union has a string, tok will be STR; and so on.

The default constructor initializes the discriminant and the union member to hold an int value of 0.

Because our union has a member with a destructor, we must define our own destructor to (conditionally) destroy the string member. Unlike ordinary members of a class type, class members that are part of a union are not automatically destroyed. The destructor has no way to know which type the union holds, so it cannot know which member to destroy.

Our destructor checks whether the object being destroyed holds a string. If so, the destructor explicitly calls the string destructor (§ 19.1.2, p. 824) to free the memory used by that string. The destructor has no work to do if the union holds a member of any of the built-in types.

Managing the Discriminant and Destroying the string

The assignment operators will set tok and assign the corresponding member of the union. Like the destructor, these members must conditionally destroy the string before assigning a new value to the union:

Click here to view code image

If the current value in the union is a string, we must destroy that string before assigning a new value to the union. We do so by calling the string destructor. Once we've cleaned up the string member, we assign the given value to the member that corresponds to the parameter type of the operator. In this case, our

parameter is an int, so we assign to ival. We update the discriminant and return.

The double and char assignment operators behave identically to the int version and are left as an exercise. The string version differs from the others because it must manage the transition to and from the string type:

Click here to view code image

```
Token &Token::operator=(const std::string &s)
{
    if (tok == STR) // if we already hold a string, just do an assignment
        sval = s;
    else
        new(&sval) string(s); // otherwise construct a string
        tok = STR; // update the discriminant
        return *this;
}
```

In this case, if the union already holds a string, we can use the normal string assignment operator to give a new value to that string. Otherwise, there is no existing string object on which to invoke the string assignment operator. Instead, we must construct a string in the memory that holds the union. We do so using placement new (§ 19.1.2, p. 824) to construct a string at the location in which sval resides. We initialize that string as a copy of our string parameter. We next update the discriminant and return.

Managing Union Members That Require Copy Control

Like the type-specific assignment operators, the copy constructor and assignment operators have to test the discriminant to know how to copy the given value. To do this common work, we'll define a member named copyUnion.

When we call copyUnion from the copy constructor, the union member will have been default-initialized, meaning that the first member of the union will have been initialized. Because our string is not the first member, we know that the union member doesn't hold a string. In the assignment operator, it is possible that the union already holds a string. We'll handle that case directly in the assignment operator. That way copyUnion can assume that if its parameter holds a string, copyUnion must construct its own string:

```
void Token::copyUnion(const Token &t)
{
    switch (t.tok) {
        case Token::INT: ival = t.ival; break;
        case Token::CHAR: cval = t.cval; break;
        case Token::DBL: dval = t.dval; break;
        // to copy a string, construct it using placement new; see (§ 19.1.2 (p. 824))
```

```
case Token::STR: new(&sval) string(t.sval); break;
}
```

This function uses a switch statement (§ 5.3.2, p. 178) to test the discriminant. For the built-in types, we assign the value to the corresponding member; if the member we are copying is a string, we construct it.

The assignment operator must handle three possibilities for its string member: Both the left-hand and right-hand operands might be a string; neither operand might be a string; or one but not both operands might be a string:

Click here to view code image

```
Token &Token::operator=(const Token &t)
{
    // if this object holds a string and t doesn't, we have to free the old string
    if (tok == STR && t.tok != STR) sval.~string();
    if (tok == STR && t.tok == STR)
        sval = t.sval; // no need to construct a new string
    else
        copyUnion(t); // will construct a string if t.tok is STR
    tok = t.tok;
    return *this;
}
```

If the union in the left-hand operand holds a string, but the union in the right-hand does not, then we have to first free the old string before assigning a new value to the union member. If both unions hold a string, we can use the normal string assignment operator to do the copy. Otherwise, we call copyUnion to do the assignment. Inside copyUnion, if the right-hand operand is a string, we'll construct a new string in the union member of the left-hand operand. If neither operand is a string, then ordinary assignment will suffice.

Exercises Section 19.6

Exercise 19.21: Write your own version of the Token class.

Exercise 19.22: Add a member of type Sales_data to your Token class.

Exercise 19.23: Add a move constructor and move assignment to Token.

Exercise 19.24: Explain what happens if we assign a Token object to itself.

Exercise 19.25: Write assignment operators that take values of each type in the union.

19.7. Local Classes

A class can be defined inside a function body. Such a class is called a local class. A

local class defines a type that is visible only in the scope in which it is defined. Unlike nested classes, the members of a local class are severely restricted.

All members, including functions, of a local class must be completely defined inside the class body. As a result, local classes are much less useful than nested classes.

In practice, the requirement that members be fully defined within the class limits the complexity of the member functions of a local class. Functions in local classes are rarely more than a few lines of code. Beyond that, the code becomes difficult for the reader to understand.

Similarly, a local class is not permitted to declare static data members, there being no way to define them.

Local Classes May Not Use Variables from the Function's Scope

The names from the enclosing scope that a local class can access are limited. A local class can access only type names, static variables (§ 6.1.1, p. 205), and enumerators defined within the enclosing local scopes. A local class may not use the ordinary local variables of the function in which the class is defined:

```
int a, val;
void foo(int val)
    static int si;
    enum Loc { a = 1024, b };
    // Bar is local to foo
    struct Bar {
         Loc locVal; // ok: uses a local type name
         int barVal;
         void fooBar(Loc l = a) // ok: default argument is Loc::a
         {
              barVal = val; // error: val is local to foo
              barVal = ::val;
                                  // ok: uses a global object
                                  // ok: uses a static local object
              barVal = si;
              locVal = b;
                                  // ok: uses an enumerator
    };
    // ...
}
```

Normal Protection Rules Apply to Local Classes

The enclosing function has no special access privileges to the private members of the local class. Of course, the local class could make the enclosing function a friend. More typically, a local class defines its members as public. The portion of a program that can access a local class is very limited. A local class is already encapsulated within the scope of the function. Further encapsulation through information hiding is often overkill.

Name Lookup within a Local Class

Name lookup within the body of a local class happens in the same manner as for other classes. Names used in the declarations of the members of the class must be in scope before the use of the name. Names used in the definition of a member can appear anywhere in the class. If a name is not found as a class member, then the search continues in the enclosing scope and then out to the scope enclosing the function itself.

Nested Local Classes

It is possible to nest a class inside a local class. In this case, the nested class definition can appear outside the local-class body. However, the nested class must be defined in the same scope as that in which the local class is defined.

Click here to view code image

As usual, when we define a member outside a class, we must indicate the scope of the name. Hence, we defined Bar::Nested, which says that Nested is a class defined in the scope of Bar.

A class nested in a local class is itself a local class, with all the attendant restrictions. All members of the nested class must be defined inside the body of the nested class itself.

19.8. Inherently Nonportable Features

To support low-level programming, C++ defines some features that are inherently **nonportable**. A nonportable feature is one that is machine specific. Programs that use nonportable features often require reprogramming when they are moved from one machine to another. The fact that the sizes of the arithmetic types vary across machines (§ 2.1.1, p. 32) is one such nonportable feature that we have already used.

In this section we'll cover two additional nonportable features that C++ inherits from C: bit-fields and the volatile qualifier. We'll also cover linkage directives, which is a nonportable feature that C++ adds to those that it inherits from C.

19.8.1. Bit-fields

A class can define a (nonstatic) data member as a **bit-field**. A bit-field holds a specified number of bits. Bit-fields are normally used when a program needs to pass binary data to another program or to a hardware device.

Note

The memory layout of a bit-field is machine dependent.

A bit-field must have integral or enumeration type (§ 19.3, p. 832). Ordinarily, we use an unsigned type to hold a bit-field, because the behavior of a signed bit-field is implementation defined. We indicate that a member is a bit-field by following the member name with a colon and a constant expression specifying the number of bits:

```
typedef unsigned int Bit;
class File {
    Bit mode: 2;
                          // mode has 2 bits
    Bit modified: 1;
                          // modified has 1 bit
    Bit prot_owner: 3; // prot_owner has 3 bits
    Bit prot_group: 3; // prot_group has 3 bits
    Bit prot_world: 3; // prot_world has 3 bits
    // operations and data members of File
public:
    // file modes specified as octal literals; see § 2.1.3 (p. 38)
    enum modes { READ = 01, WRITE = 02, EXECUTE = 03 };
    File & open(modes);
    void close();
    void write();
    bool isRead() const;
    void setWrite();
```

};

The mode bit-field has two bits, modified only one, and the other members each have three bits. Bit-fields defined in consecutive order within the class body are, if possible, packed within adjacent bits of the same integer, thereby providing for storage compaction. For example, in the preceding declaration, the five bit-fields will (probably) be stored in a single unsigned int. Whether and how the bits are packed into the integer is machine dependent.

The address-of operator (&) cannot be applied to a bit-field, so there can be no pointers referring to class bit-fields.

Warning

Ordinarily it is best to make a bit-field an unsigned type. The behavior of bit-fields stored in a signed type is implementation defined.

Using Bit-fields

A bit-field is accessed in much the same way as the other data members of a class:

Click here to view code image

```
void File::write()
    modified = 1;
    // ...
void File::close()
    if (modified)
         // ... save contents
```

Bit-fields with more than one bit are usually manipulated using the built-in bitwise operators (§ 4.8, p. 152):

Click here to view code image

```
File &File::open(File::modes m)
    mode = READ; // set the READ bit by default
     // other processing
     if (m & WRITE) // if opening READ and WRITE
     // processing to open the file in read/write mode
    return *this;
```

Classes that define bit-field members also usually define a set of inline member

functions to test and set the value of the bit-field:

Click here to view code image

```
inline bool File::isRead() const { return mode & READ; }
inline void File::setWrite() { mode |= WRITE; }
```

19.8.2. volatile Qualifier

Warning

The precise meaning of volatile is inherently machine dependent and can be understood only by reading the compiler documentation. Programs that use volatile usually must be changed when they are moved to new machines or compilers.

Programs that deal directly with hardware often have data elements whose value is controlled by processes outside the direct control of the program itself. For example, a program might contain a variable updated by the system clock. An object should be declared volatile when its value might be changed in ways outside the control or detection of the program. The volatile keyword is a directive to the compiler that it should not perform optimizations on such objects.

The volatile qualifier is used in much the same way as the const qualifier. It is an additional modifier to a type:

Click here to view code image

```
volatile int display_register; // int value that might change
volatile Task *curr task; // curr task points to a volatile object
volatile int iax[max size]; // each element in iax is volatile
volatile Screen bitmapBuf; // each member of bitmapBuf is volatile
```

There is no interaction between the const and volatile type qualifiers. A type can be both const and volatile, in which case it has the properties of both.

In the same way that a class may define const member functions, it can also define member functions as volatile. Only volatile member functions may be called on volatile objects.

§ 2.4.2 (p. 62) described the interactions between the const qualifier and pointers. The same interactions exist between the volatile qualifier and pointers. We can declare pointers that are volatile, pointers to volatile objects, and pointers that are volatile that point to volatile objects:

As with const, we may assign the address of a volatile object (or copy a pointer to a volatile type) only to a pointer to volatile. We may use a volatile object to initialize a reference only if the reference is volatile.

Synthesized Copy Does Not Apply to volatile Objects

One important difference between the treatment of const and volatile is that the synthesized copy/move and assignment operators cannot be used to initialize or assign from a volatile object. The synthesized members take parameters that are references to (nonvolatile) const, and we cannot bind a nonvolatile reference to a volatile object.

If a class wants to allow volatile objects to be copied, moved, or assigned, it must define its own versions of the copy or move operation. As one example, we might write the parameters as const volatile references, in which case we can copy or assign from any kind of Foo:

Click here to view code image

```
class Foo {
public:
    Foo(const volatile Foo&); // copy from a volatile object
    // assign from a volatile object to a nonvolatile object
    Foo& operator=(volatile const Foo&);
    // assign from a volatile object to a volatile object
    Foo& operator=(volatile const Foo&) volatile;
    // remainder of class Foo
};
```

Although we can define copy and assignment for volatile objects, a deeper question is whether it makes any sense to copy a volatile object. The answer to that question depends intimately on the reason for using volatile in any particular program.

19.8.3. Linkage Directives: extern "C"

C++ programs sometimes need to call functions written in another programming language. Most often, that other language is C. Like any name, the name of a function

written in another language must be declared. As with any function, that declaration must specify the return type and parameter list. The compiler checks calls to functions written in another language in the same way that it handles ordinary C++ functions. However, the compiler typically must generate different code to call functions written in other languages. C++ uses **linkage directives** to indicate the language used for any non-C++ function.

Note

Mixing C++ with code written in any other language, including C, requires access to a compiler for that language that is compatible with your C++ compiler.

Declaring a Non-C++ Function

A linkage directive can have one of two forms: single or compound. Linkage directives may not appear inside a class or function definition. The same linkage directive must appear on every declaration of a function.

As an example, the following declarations shows how some of the C functions in the cstring header might be declared:

Click here to view code image

```
// illustrative linkage directives that might appear in the C++ header <cstring>
// single-statement linkage directive
extern "C" size_t strlen(const char *);
// compound-statement linkage directive
extern "C" {
   int strcmp(const char*, const char*);
   char *strcat(char*, const char*);
}
```

The first form of a linkage directive consists of the extern keyword followed by a string literal, followed by an "ordinary" function declaration.

The string literal indicates the language in which the function is written. A compiler is required to support linkage directives for C. A compiler may provide linkage specifications for other languages, for example, extern "Ada", extern "FORTRAN", and so on.

Linkage Directives and Headers

We can give the same linkage to several functions at once by enclosing their declarations inside curly braces following the linkage directive. These braces serve to group the declarations to which the linkage directive applies. The braces are otherwise

ignored, and the names of functions declared within the braces are visible as if the functions were declared outside the braces.

The multiple-declaration form can be applied to an entire header file. For example, the C++ cstring header might look like

Click here to view code image

```
// compound-statement linkage directive
extern "C" {
#include <string.h> // C functions that manipulate C-style strings
}
```

When a #include directive is enclosed in the braces of a compound-linkage directive, all ordinary function declarations in the header file are assumed to be functions written in the language of the linkage directive. Linkage directives can be nested, so if a header contains a function with its own linkage directive, the linkage of that function is unaffected.

Note

The functions that C++ inherits from the C library are permitted to be defined as C functions but are not required to be C functions—it's up to each C++ implementation to decide whether to implement the C library functions in C or C++.

Pointers to extern "C" Functions

The language in which a function is written is part of its type. Hence, every declaration of a function defined with a linkage directive must use the same linkage directive. Moreover, pointers to functions written in other languages must be declared with the same linkage directive as the function itself:

Click here to view code image

```
// pf points to a C function that returns void and takes an int
extern "C" void (*pf)(int);
```

When pf is used to call a function, the function call is compiled assuming that the call is to a C function.

A pointer to a C function does not have the same type as a pointer to a C++ function. A pointer to a C function cannot be initialized or be assigned to point to a C++ function (and vice versa). As with any other type mismatch, it is an error to try to assign two pointers with different linkage directives:

```
void (*pf1)(int);
                                   // points to a C++ function
extern "C" void (*pf2)(int); // points to a C function
pf1 = pf2; // error: pf1 and pf2 have different types
```

Warning

Some C++ compilers may accept the preceding assignment as a language extension, even though, strictly speaking, it is illegal.

Linkage Directives Apply to the Entire Declaration

When we use a linkage directive, it applies to the function and any function pointers used as the return type or as a parameter type:

Click here to view code image

```
// fl is a C function; its parameter is a pointer to a C function
extern "C" void f1(void(*)(int));
```

This declaration says that f1 is a C function that doesn't return a value. It has one parameter, which is a pointer to a function that returns nothing and takes a single int parameter. The linkage directive applies to the function pointer as well as to f1. When we call f1, we must pass it the name of a C function or a pointer to a C function.

Because a linkage directive applies to all the functions in a declaration, we must use a type alias (§ 2.5.1, p. 67) if we wish to pass a pointer to a C function to a C++ function:

Click here to view code image

```
// FC is a pointer to a C function
extern "C" typedef void FC(int);
// f2 is a C++ function with a parameter that is a pointer to a C function
void f2(FC *);
```

Exporting Our C++ Functions to Other Languages

By using the linkage directive on a function definition, we can make a C++ function available to a program written in another language:

```
// the calc function can be called from C programs
extern "C" double calc(double dparm) { /* ... */ }
```

When the compiler generates code for this function, it will generate code appropriate to the indicated language.

It is worth noting that the parameter and return types in functions that are shared across languages are often constrained. For example, we can almost surely not write a function that passes objects of a (nontrivial) C++ class to a C program. The C program won't know about the constructors, destructors, or other class-specific operations.

Preprocessor Support for Linking to C

To allow the same source file to be compiled under either C or C++, the preprocessor defines $_ _cplusplus$ (two underscores) when we compile C++. Using this variable, we can conditionally include code when we are compiling C++:

Click here to view code image

```
#ifdef __cplusplus
// ok: we're compiling C++
extern "C"
#endif
int strcmp(const char*, const char*);
```

Overloaded Functions and Linkage Directives

The interaction between linkage directives and function overloading depends on the target language. If the language supports overloaded functions, then it is likely that a compiler that implements linkage directives for that language would also support overloading of these functions from C++.

The C language does not support function overloading, so it should not be a surprise that a C linkage directive can be specified for only one function in a set of overloaded functions:

Click here to view code image

```
// error: two extern "C" functions with the same name
extern "C" void print(const char*);
extern "C" void print(int);
```

If one function among a set of overloaded functions is a C function, the other functions must all be C++ functions:

```
class SmallInt { /* ... */ };
class BigNum { /* ... */ };
```

```
// the C function can be called from C and C++ programs
// the C++ functions overload that function and are callable from C++
extern "C" double calc(double);
extern SmallInt calc(const SmallInt&);
extern BigNum calc(const BigNum&);
```

The C version of calc can be called from C programs and from C++ programs. The additional functions are C++ functions with class parameters that can be called only from C++ programs. The order of the declarations is not significant.

Exercises Section 19.8.3

Exercise 19.26: Explain these declarations and indicate whether they are legal:

Click here to view code image

```
extern "C" int compute(int *, int);
extern "C" double compute(double *, double);
```

Chapter Summary

C++ provides several specialized facilities that are tailored to particular kinds of problems.

Some applications need to take control of how memory is allocated. They can do so by defining their own versions—either class specific or global—of the library operator new and operator delete functions. If the application defines its own versions of these functions, new and delete expressions will use the application-defined version.

Some programs need to directly interrogate the dynamic type of an object at run time. Run-time type identification (RTTI) provides language-level support for this kind of programming. RTTI applies only to classes that define virtual functions; type information for types that do not define virtual functions is available but reflects the static type.

When we define a pointer to a class member, the pointer type also encapsulates the type of the class containing the member to which the pointer points. A pointer to member may be bound to any member of the class that has the appropriate type. When we dereference a pointer to member, we must supply an object from which to fetch the member.

C++ defines several additional aggregate types:

• Nested classes, which are classes defined in the scope of another class. Such classes are often defined as implementation classes of their enclosing class.

- unions are a special kind of class that may define several data members, but at any point in time, only one member may have a value. unions are most often nested inside another class type.
- Local classes, which are defined inside a function. All members of a local class must be defined in the class body. There are no static data members of a local class.

C++ also supports several inherently nonportable features, including bit-fields and volatile, which make it easier to interface to hardware, and linkage directives, which make it easier to interface to programs written in other languages.

Defined Terms

anonymous union Unnamed union that is not used to define an object. Members of an anonymous union become members of the surrounding scope. These unions may not have member functions and may not have private or protected members.

bit-field Class member with a integral type that specifies the number of bits to allocate to the member. Bit-fields defined in consecutive order in the class are, if possible, compacted into a common integral value.

discriminant Programming technique that uses an object to determine which actual type is held in a union at any given time.

dynamic_cast Operator that performs a checked cast from a base type to a derived type. When the base type has at least one virtual function, the operator checks the dynamic type of the object to which the reference or pointer is bound. If the object type is the same as the type of the cast (or a type derived from that type), then the cast is done. Otherwise, a zero pointer is returned for a pointer cast, or an exception is thrown for a cast to a reference type.

enumeration Type that groups a set of named integral constants.

enumerator Member of an enumeration. Enumerators are const and may be used where integral constant expressions are required.

free Low-level memory deallocation function defined in cstdlib. free may be used *only* to free memory allocated by malloc.

linkage directive Mechanism used to allow functions written in a different language to be called from a C++ program. All compilers must support calling C and C++ functions. It is compiler dependent whether any other languages are supported.

local class Class defined inside a function. A local class is visible only inside the function in which it is defined. All members of the class must be defined inside

the class body. There can be no static members of a local class. Local class members may not access the nonstatic variables defined in the enclosing function. They may use type names, static variables, or enumerators defined in the enclosing function.

malloc Low-level memory allocation function defined in cstdlib. Memory allocated by malloc must be freed by free.

mem_fn Library class template that generates a callable object from a given pointer to member function.

nested class Class defined inside another class. A nested class is defined inside its enclosing scope: Nested-class names must be unique within the class scope in which they are defined but can be reused in scopes outside the enclosing class. Access to the nested class outside the enclosing class requires use of the scope operator to specify the scope(s) in which the class is nested.

nested type Synonym for nested class.

nonportable Features that are inherently machine specific and may require change when a program is ported to another machine or compiler.

operator delete Library function that frees untyped, unconstructed memory allocated by operator new. The library operator delete[] frees memory used to hold an array that was allocated by operator new[].

operator new Library function that allocates untyped, unconstructed memory of a given size. The library function operator new[] allocates raw memory for arrays. These library functions provide a more primitive allocation mechanism than the library allocator class. Modern C++ programs should use the allocator classes rather than these library functions.

placement new expression Form of new that constructs its object in specified memory. It does no allocation; instead, it takes an argument that specifies where the object should be constructed. It is a lower-level analog of the behavior provided by the construct member of the allocator class.

pointer to member Pointer that encapsulates the class type as well as the member type to which the pointer points. The definition of a pointer to member must specify the class name as well as the type of the member(s) to which the pointer may point:

```
T C::*pmem = &C::member;
```

This statement defines pmem as a pointer that can point to members of the class named C that have type T and initializes pmem to point to the member in C named member. To use the pointer, we must supply an object or pointer to type C:

```
classobj.*pmem;
```

classptr->*pmem;

fetches member from the object classobj of the object pointed to by classptr.

run-time type identification Language and library facilities that allow the dynamic type of a reference or pointer to be obtained at run time. The RTTI operators, typeid and dynamic_cast, provide the dynamic type only for references or pointers to class types with virtual functions. When applied to other types, the type returned is the static type of the reference or pointer.

scoped enumeration New-style enumeration in which the enumerator are not accessible directly in the surrounding scope.

typeid operator Unary operator that returns a reference to an object of the library type named type_info that describes the type of the given expression. When the expression is an object of a type that has virtual functions, then the dynamic type of the expression is returned; such expressions are evaluated at run time. If the type is a reference, pointer, or other type that does not define virtual functions, then the type returned is the static type of the reference, pointer, or object; such expressions are not evaluated.

type_info Library type returned by the typeid operator. The type_info class is inherently machine dependent, but must provide a small set of operations, including a name function that returns a character string representing the type's name. type_info objects may not be copied, moved, or assigned.

union Classlike aggregate type that may define multiple data members, only one of which can have a value at any one point. Unions may have member functions, including constructors and destructors. A union may not serve as a base class. Under the new standard, unions can have members that are class types that define their own copy-control members. Such unions obtain deleted copy control if they do not themselves define the corresponding copy-control functions.

unscoped enumeration Enumeration in which the enumerators are accessible in the surrounding scope.

volatile Type qualifier that signifies to the compiler that a variable might be changed outside the direct control of the program. It is a signal to the compiler that it may not perform certain optimizations.
