"call" objects of such classes just as if they were functions. We'll also look at new library facilities that make it easy to use different types of callable objects in a uniform way.

This chapter concludes by looking at another special kind of class member function—conversion operators. These operators define implicit conversions from objects of class type. The compiler applies these conversions in the same contexts—and for the same reasons—as it does with conversions among the built-in types.

The last two chapters in this part cover how C++ supports object-oriented and generic programming.

Chapter 15 covers inheritance and dynamic binding. Along with data abstraction, inheritance and dynamic binding are fundamental to object-oriented programming. Inheritance makes it easier for us to define related types and dynamic binding lets us write type-indepenent code that can ignore the differences among types that are related by inheritance.

Chapter 16 covers function and class templates. Templates let us write generic classes and functions that are type-independent. A number of new template-related features were introduced by the new standard: variadic templates, template type aliases, and new ways to control instantiation.

Writing our own object-oriented or generic types requires a fairly good understanding of C++. Fortunately, we can use object-oriented and generic types without understanding the details of how to build them. For example, the standard library uses the facilities we'll study in Chapters 15 and 16 extensively, and we've used the library types and algorithms without needing to know how they are implemented.

Readers, therefore, should understand that Part III covers fairly advanced topics. Writing templates or object-oriented classes requires a good understanding of the basics of C++ and a good grasp of how to define more basic classes.

Chapter Summary

Defined Terms

As we saw in Chapter 7, each class defines a new type and defines the operations that objects of that type can perform. In that chapter, we also learned that classes can define constructors, which control what happens when objects of the class type are created.

In this chapter we'll learn how classes can control what happens when objects of the class type are copied, assigned, moved, or destroyed. Classes control these actions through special member functions: the copy constructor, move constructor, copyassignment operator, move-assignment operator, and destructor.

When we define a class, we specify—explicitly or implicitly—what happens when objects of that class type are copied, moved, assigned, and destroyed. A class controls these operations by defining five special member functions: copy constructor, copyassignment operator, move constructor, move-assignment operator, and **destructor**. The copy and move constructors define what happens when an object is initialized from another object of the same type. The copy- and move-assignment operators define what happens when we assign an object of a class type to another object of that same class type. The destructor defines what happens when an object of the type ceases to exist. Collectively, we'll refer to these operations as copy control.

If a class does not define all of the copy-control members, the compiler automatically defines the missing operations. As a result, many classes can ignore copy control (§ 7.1.5, p. 267). However, for some classes, relying on the default definitions leads to disaster. Frequently, the hardest part of implementing copy-control operations is recognizing when we need to define them in the first place.

Warning

Copy control is an essential part of defining any C++ class. Programmers new to C++ are often confused by having to define what happens when objects are copied, moved, assigned, or destroyed. This confusion is compounded because if we do not explicitly define these operations, the compiler defines them for us—although the compiler-defined versions might not behave as we intend.

13.1. Copy, Assign, and Destroy

We'll start by covering the most basic operations, which are the copy constructor, copy-assignment operator, and destructor. We'll cover the move operations (which were introduced by the new standard) in § 13.6 (p. 531).

13.1.1. The Copy Constructor

A constructor is the copy constructor if its first parameter is a reference to the class type and any additional parameters have default values:

Click here to view code image

For reasons we'll explain shortly, the first parameter must be a reference type. That parameter is almost always a reference to const, although we can define the copy constructor to take a reference to nonconst. The copy constructor is used implicitly in several circumstances. Hence, the copy constructor usually should not be explicit (§ 7.5.4, p. 296).

The Synthesized Copy Constructor

When we do not define a copy constructor for a class, the compiler synthesizes one for us. Unlike the synthesized default constructor (§ 7.1.4, p. 262), a copy constructor is synthesized even if we define other constructors.

As we'll see in § 13.1.6 (p. 508), the **synthesized copy constructor** for some classes prevents us from copying objects of that class type. Otherwise, the synthesized copy constructor **memberwise copies** the members of its argument into the object being created (§ 7.1.5, p. 267). The compiler copies each nonstatic member in turn from the given object into the one being created.

The type of each member determines how that member is copied: Members of class type are copied by the copy constructor for that class; members of built-in type are copied directly. Although we cannot directly copy an array (§ 3.5.1, p. 114), the synthesized copy constructor copies members of array type by copying each element. Elements of class type are copied by using the elements' copy constructor.

As an example, the synthesized copy constructor for our Sales_data class is equivalent to:

```
class Sales_data {
public:
    // other members and constructors as before
    // declaration equivalent to the synthesized copy constructor
    Sales_data(const Sales_data&);
private:
```

Copy Initialization

We are now in a position to fully understand the differences between direct initialization and copy initialization (§ 3.2.1, p. 84):

Click here to view code image

When we use direct initialization, we are asking the compiler to use ordinary function matching (§ 6.4, p. 233) to select the constructor that best matches the arguments we provide. When we use **copy initialization**, we are asking the compiler to copy the right-hand operand into the object being created, converting that operand if necessary (§ 7.5.4, p. 294).

Copy initialization ordinarily uses the copy constructor. However, as we'll see in § 13.6.2 (p. 534), if a class has a move constructor, then copy initialization sometimes uses the move constructor instead of the copy constructor. For now, what's useful to know is when copy initialization happens and that copy initialization requires either the copy constructor or the move constructor.

Copy initialization happens not only when we define variables using an =, but also when we

- Pass an object as an argument to a parameter of nonreference type
- Return an object from a function that has a nonreference return type
- Brace initialize the elements in an array or the members of an aggregate class (§ 7.5.5, p. 298)

Some class types also use copy initialization for the objects they allocate. For example, the library containers copy initialize their elements when we initialize the container, or when we call an insert or push member (§ 9.3.1, p. 342). By contrast, elements created by an emplace member are direct initialized (§ 9.3.1, p. 345).

Parameters and Return Values

During a function call, parameters that have a nonreference type are copy initialized (§ 6.2.1, p. 209). Similarly, when a function has a nonreference return type, the return value is used to copy initialize the result of the call operator at the call site (§ 6.3.2, p. 224).

The fact that the copy constructor is used to initialize nonreference parameters of class type explains why the copy constructor's own parameter must be a reference. If that parameter were not a reference, then the call would never succeed—to call the copy constructor, we'd need to use the copy constructor to copy the argument, but to copy the argument, we'd need to call the copy constructor, and so on indefinitely.

Constraints on Copy Initialization

As we've seen, whether we use copy or direct initialization matters if we use an initializer that requires conversion by an explicit constructor (§ 7.5.4, p. 296):

Click here to view code image

```
vector<int> v1(10); // ok: direct initialization
vector<int> v2 = 10; // error: constructor that takes a size is explicit
void f(vector<int>); // f's parameter is copy initialized
f(10); // error: can't use an explicit constructor to copy an argument
f(vector<int>(10)); // ok: directly construct a temporary vector from an int
```

Directly initializing v1 is fine, but the seemingly equivalent copy initialization of v2 is an error, because the vector constructor that takes a single size parameter is explicit. For the same reasons that we cannot copy initialize v2, we cannot implicitly use an explicit constructor when we pass an argument or return a value from a function. If we want to use an explicit constructor, we must do so explicitly, as in the last line of the example above.

The Compiler Can Bypass the Copy Constructor

During copy initialization, the compiler is permitted (but not obligated) to skip the copy/move constructor and create the object directly. That is, the compiler is permitted to rewrite

Click here to view code image

```
string null_book = "9-999-99999-9"; // copy initialization
into
```

```
string null_book("9-999-99999-9"); // compiler omits the copy constructor
```

However, even if the compiler omits the call to the copy/move constructor, the copy/move constructor must exist and must be accessible (e.g., not private) at that point in the program.

Exercises Section 13.1.1

Exercise 13.1: What is a copy constructor? When is it used?

Exercise 13.2: Explain why the following declaration is illegal:

Click here to view code image

```
Sales_data::Sales_data(Sales_data rhs);
```

Exercise 13.3: What happens when we copy a StrBlob? What about StrBlobPtrs?

Exercise 13.4: Assuming Point is a class type with a public copy constructor, identify each use of the copy constructor in this program fragment:

Click here to view code image

```
Point global;
Point foo_bar(Point arg)
{
    Point local = arg, *heap = new Point(global);
    *heap = local;
    Point pa[ 4 ] = { local, *heap };
    return *heap;
}
```

Exercise 13.5: Given the following sketch of a class, write a copy constructor that copies all the members. Your constructor should dynamically allocate a new string (§ 12.1.2, p. 458) and copy the object to which ps points, rather than copying ps itself.

```
class HasPtr {
public:
    HasPtr(const std::string &s = std::string()):
        ps(new std::string(s)), i(0) { }
private:
    std::string *ps;
    int i;
};
```

13.1.2. The Copy-Assignment Operator

Just as a class controls how objects of that class are initialized, it also controls how objects of its class are assigned:

Click here to view code image

```
Sales data trans, accum;
trans = accum; // uses the Sales_data copy-assignment operator
```

As with the copy constructor, the compiler synthesizes a copy-assignment operator if the class does not define its own.

Introducing Overloaded Assignment

Before we look at the synthesized assignment operator, we need to know a bit about overloaded operators, which we cover in detail in Chapter 14.

Overloaded operators are functions that have the name operator followed by the symbol for the operator being defined. Hence, the assignment operator is a function named operator=. Like any other function, an operator function has a return type and a parameter list.

The parameters in an overloaded operator represent the operands of the operator. Some operators, assignment among them, must be defined as member functions. When an operator is a member function, the left-hand operand is bound to the implicit this parameter (§ 7.1.2, p. 257). The right-hand operand in a binary operator, such as assignment, is passed as an explicit parameter.

The copy-assignment operator takes an argument of the same type as the class:

Click here to view code image

```
class Foo {
public:
    Foo& operator=(const Foo&); // assignment operator
   // ...
};
```

To be consistent with assignment for the built-in types (§ 4.4, p. 145), assignment operators usually return a reference to their left-hand operand. It is also worth noting that the library generally requires that types stored in a container have assignment operators that return a reference to the left-hand operand.

Best Practices

Assignment operators ordinarily should return a reference to their left-hand

operand.

The Synthesized Copy-Assignment Operator

Just as it does for the copy constructor, the compiler generates a **synthesized copy-assignment operator** for a class if the class does not define its own. Analogously to the copy constructor, for some classes the synthesized copy-assignment operator disallows assignment (§ 13.1.6, p. 508). Otherwise, it assigns each nonstatic member of the right-hand object to the corresponding member of the left-hand object using the copy-assignment operator for the type of that member. Array members are assigned by assigning each element of the array. The synthesized copy-assignment operator returns a reference to its left-hand object.

As an example, the following is equivalent to the synthesized Sales_data copyassignment operator:

Click here to view code image

Exercises Section 13.1.2

Exercise 13.6: What is a copy-assignment operator? When is this operator used? What does the synthesized copy-assignment operator do? When is it synthesized?

Exercise 13.7: What happens when we assign one StrBlob to another? What about StrBlobPtrs?

Exercise 13.8: Write the assignment operator for the HasPtr class from exercise 13.5 in § 13.1.1 (p. 499). As with the copy constructor, your assignment operator should copy the object to which ps points.

13.1.3. The Destructor

The destructor operates inversely to the constructors: Constructors initialize the nonstatic data members of an object and may do other work; destructors do whatever work is needed to free the resources used by an object and destroy the nonstatic data members of the object.

The destructor is a member function with the name of the class prefixed by a tilde (~). It has no return value and takes no parameters:

```
class Foo {
public:
    ~Foo();  // destructor
    // ...
};
```

Because it takes no parameters, it cannot be overloaded. There is always only one destructor for a given class.

What a Destructor Does

Just as a constructor has an initialization part and a function body (§ 7.5.1, p. 288), a destructor has a function body and a destruction part. In a constructor, members are initialized before the function body is executed, and members are initialized in the same order as they appear in the class. In a destructor, the function body is executed first and then the members are destroyed. Members are destroyed in reverse order from the order in which they were initialized.

The function body of a destructor does whatever operations the class designer wishes to have executed subsequent to the last use of an object. Typically, the destructor frees resources an object allocated during its lifetime.

In a destructor, there is nothing akin to the constructor initializer list to control how members are destroyed; the destruction part is implicit. What happens when a member is destroyed depends on the type of the member. Members of class type are destroyed by running the member's own destructor. The built-in types do not have destructors, so nothing is done to destroy members of built-in type.

Note

The implicit destruction of a member of built-in pointer type does *not* delete the object to which that pointer points.

Unlike ordinary pointers, the smart pointers (§ 12.1.1, p. 452) are class types and have destructors. As a result, unlike ordinary pointers, members that are smart pointers are automatically destroyed during the destruction phase.

When a Destructor Is Called

The destructor is used automatically whenever an object of its type is destroyed:

- Variables are destroyed when they go out of scope.
- Members of an object are destroyed when the object of which they are a part is destroyed.
- Elements in a container—whether a library container or an array—are destroyed when the container is destroyed.
- Dynamically allocated objects are destroyed when the delete operator is applied to a pointer to the object (§ 12.1.2, p. 460).
- Temporary objects are destroyed at the end of the full expression in which the temporary was created.

Because destructors are run automatically, our programs can allocate resources and (usually) not worry about when those resources are released.

For example, the following fragment defines four Sales_data objects:

Click here to view code image

Each of these objects contains a string member, which allocates dynamic memory to contain the characters in its bookNo member. However, the only memory our code has to manage directly is the object we directly allocated. Our code directly frees only the dynamically allocated object bound to p.

The other Sales_data objects are automatically destroyed when they go out of scope. When the block ends, vec, p2, and item all go out of scope, which means that the vector, shared_ptr, and Sales_data destructors will be run on those objects, respectively. The vector destructor will destroy the element we pushed onto vec. The shared_ptr destructor will decrement the reference count of the object to which p2 points. In this example, that count will go to zero, so the shared_ptr destructor will delete the Sales_data object that p2 allocated.

In all cases, the Sales_data destructor implicitly destroys the bookNo member. Destroying bookNo runs the string destructor, which frees the memory used to store the ISBN.

Note

The destructor is *not* run when a reference or a pointer to an object goes out of scope.

The Synthesized Destructor

The compiler defines a **synthesized destructor** for any class that does not define its own destructor. As with the copy constructor and the copy-assignment operator, for some classes, the synthesized destructor is defined to disallow objects of the type from being destroyed (§ 13.1.6, p. 508). Otherwise, the synthesized destructor has an empty function body.

For example, the synthesized Sales_data destructor is equivalent to:

Click here to view code image

```
class Sales_data {
public:
    // no work to do other than destroying the members, which happens automatically
    ~Sales_data() { }
    // other members as before
};
```

The members are automatically destroyed after the (empty) destructor body is run. In particular, the string destructor will be run to free the memory used by the bookNo member.

It is important to realize that the destructor body does not directly destroy the members themselves. Members are destroyed as part of the implicit destruction phase that follows the destructor body. A destructor body executes *in addition to* the memberwise destruction that takes place as part of destroying an object.

13.1.4. The Rule of Three/Five

As we've seen, there are three basic operations to control copies of class objects: the copy constructor, copy-assignment operator, and destructor. Moreover, as we'll see in § 13.6 (p. 531), under the new standard, a class can also define a move constructor and move-assignment operator.

Exercises Section 13.1.3

Exercise 13.9: What is a destructor? What does the synthesized destructor do? When is a destructor synthesized?

Exercise 13.10: What happens when a StrBlob object is destroyed? What about a StrBlobPtr?

Exercise 13.11: Add a destructor to your HasPtr class from the previous exercises.

Exercise 13.12: How many destructor calls occur in the following code fragment?

Click here to view code image

```
bool fcn(const Sales_data *trans, Sales_data accum)
{
    Sales_data item1(*trans), item2(accum);
    return item1.isbn() != item2.isbn();
}
```

Exercise 13.13: A good way to understand copy-control members and constructors is to define a simple class with these members in which each member prints its name:

Click here to view code image

```
struct X {
    X() {std::cout << "X()" << std::endl;}
        X(const X&) {std::cout << "X(const X&)" << std::endl;}
};</pre>
```

Add the copy-assignment operator and destructor to x and write a program using x objects in various ways: Pass them as nonreference and reference parameters; dynamically allocate them; put them in containers; and so forth. Study the output until you are certain you understand when and why each copy-control member is used. As you read the output, remember that the compiler can omit calls to the copy constructor.

There is no requirement that we define all of these operations: We can define one or two of them without having to define all of them. However, ordinarily these operations should be thought of as a unit. In general, it is unusual to need one without needing to define them all.

Classes That Need Destructors Need Copy and Assignment

One rule of thumb to use when you decide whether a class needs to define its own versions of the copy-control members is to decide first whether the class needs a destructor. Often, the need for a destructor is more obvious than the need for the copy constructor or assignment operator. If the class needs a destructor, it almost surely needs a copy constructor and copy-assignment operator as well.

The HasPtr class that we have used in the exercises is a good example (§ 13.1.1, p. 499). That class allocates dynamic memory in its constructor. The synthesized destructor will not delete a data member that is a pointer. Therefore, this class needs to define a destructor to free the memory allocated by its constructor.

What may be less clear—but what our rule of thumb tells us—is that HasPtr also needs a copy constructor and copy-assignment operator.

Consider what would happen if we gave HasPtr a destructor but used the synthesized versions of the copy constructor and copy-assignment operator:

Click here to view code image

```
class HasPtr {
public:
    HasPtr(const std::string &s = std::string()):
        ps(new std::string(s)), i(0) { }
    ~HasPtr() { delete ps; }
    // WRONG: HasPtr needs a copy constructor and copy-assignment operator
    // other members as before
};
```

In this version of the class, the memory allocated in the constructor will be freed when a HasPtr object is destroyed. Unfortunately, we have introduced a serious bug! This version of the class uses the synthesized versions of copy and assignment. Those functions copy the pointer member, meaning that multiple HasPtr objects may be pointing to the same memory:

Click here to view code image

```
HasPtr f(HasPtr hp) // HasPtr passed by value, so it is copied
{
    HasPtr ret = hp; // copies the given HasPtr
    // process ret
    return ret; // ret and hp are destroyed
}
```

When f returns, both hp and ret are destroyed and the HasPtr destructor is run on each of these objects. That destructor will delete the pointer member in ret and in hp. But these objects contain the same pointer value. This code will delete that pointer twice, which is an error (§ 12.1.2, p. 462). What happens is undefined.

In addition, the caller of f may still be using the object that was passed to f:

```
HasPtr p("some values");
f(p); // when f completes, the memory to which p.ps points is freed
HasPtr q(p); // now both p and q point to invalid memory!
```

The memory to which p (and q) points is no longer valid. It was returned to the system when hp (or ret!) was destroyed.

If a class needs a destructor, it almost surely also needs the copy-assignment operator and a copy constructor.

Classes That Need Copy Need Assignment, and Vice Versa

Although many classes need to define all of (or none of) the copy-control members, some classes have work that needs to be done to copy or assign objects but has no need for the destructor.

As an example, consider a class that gives each object its own, unique serial number. Such a class would need a copy constructor to generate a new, distinct serial number for the object being created. That constructor would copy all the other data members from the given object. This class would also need its own copy-assignment operator to avoid assigning to the serial number of the left-hand object. However, this class would have no need for a destructor.

This example gives rise to a second rule of thumb: If a class needs a copy constructor, it almost surely needs a copy-assignment operator. And vice versa—if the class needs an assignment operator, it almost surely needs a copy constructor as well. Nevertheless, needing either the copy constructor or the copy-assignment operator does not (necessarily) indicate the need for a destructor.

Exercises Section 13.1.4

Exercise 13.14: Assume that numbered is a class with a default constructor that generates a unique serial number for each object, which is stored in a data member named mysn. Assuming numbered uses the synthesized copycontrol members and given the following function:

Click here to view code image

```
void f (numbered s) { cout << s.mysn << endl; }
what output does the following code produce?</pre>
```

```
numbered a, b = a, c = b; f(a); f(b); f(c);
```

Exercise 13.15: Assume numbered has a copy constructor that generates a new serial number. Does that change the output of the calls in the previous exercise? If so, why? What output gets generated?

Exercise 13.16: What if the parameter in f were const numbered&? Does that change the output? If so, why? What output gets generated?

Exercise 13.17: Write versions of numbered and f corresponding to the previous three exercises and check whether you correctly predicted the output.

13.1.5. Using = default

We can explicitly ask the compiler to generate the synthesized versions of the copycontrol members by defining them as = default (§ 7.1.4, p. 264):

Click here to view code image

```
class Sales_data {
public:
    // copy control; use defaults
    Sales_data() = default;
    Sales_data(const Sales_data&) = default;
    Sales_data& operator=(const Sales_data &);
    ~Sales_data() = default;
    // other members as before
};
Sales_data& Sales_data::operator=(const Sales_data&)
default;
```

When we specify = default on the declaration of the member inside the class body, the synthesized function is implicitly inline (just as is any other member function defined in the body of the class). If we do not want the synthesized member to be an inline function, we can specify = default on the member's definition, as we do in the definition of the copy-assignment operator.

We can use = default only on member functions that have a synthesized version (i.e., the default constructor or a copy-control member).

13.1.6. Preventing Copies

***** Best Practices

Most classes should define—either implicitly or explicitly—the default and copy constructors and the copy-assignment operator.

Although most classes should (and generally do) define a copy constructor and a copy-assignment operator, for some classes, there really is no sensible meaning for these operations. In such cases, the class must be defined so as to prevent copies or assignments from being made. For example, the iostream classes prevent copying to avoid letting multiple objects write to or read from the same IO buffer. It might seem that we could prevent copies by not defining the copy-control members. However, this strategy doesn't work: If our class doesn't define these operations, the compiler will synthesize them.

Defining a Function as Deleted

Under the new standard, we can prevent copies by defining the copy constructor and copy-assignment operator as **deleted functions**. A deleted function is one that is declared but may not be used in any other way. We indicate that we want to define a function as deleted by following its parameter list with = delete:

Click here to view code image

```
struct NoCopy {
    NoCopy() = default; // use the synthesized default constructor
    NoCopy(const NoCopy&) = delete; // no copy
    NoCopy & operator = (const NoCopy&) = delete; // no assignment
    ~NoCopy() = default; // use the synthesized destructor
    // other members
};
```

The = delete signals to the compiler (and to readers of our code) that we are intentionally *not defining* these members.

Unlike = default, = delete must appear on the first declaration of a deleted function. This difference follows logically from the meaning of these declarations. A defaulted member affects only what code the compiler generates; hence the = default is not needed until the compiler generates code. On the other hand, the compiler needs to know that a function is deleted in order to prohibit operations that attempt to use it.

Also unlike = default, we can specify = delete on any function (we can use =

default only on the default constructor or a copy-control member that the compiler can synthesize). Although the primary use of deleted functions is to suppress the copy-control members, deleted functions are sometimes also useful when we want to guide the function-matching process.

The Destructor Should Not be a Deleted Member

It is worth noting that we did not delete the destructor. If the destructor is deleted, then there is no way to destroy objects of that type. The compiler will not let us define variables or create temporaries of a type that has a deleted destructor. Moreover, we cannot define variables or temporaries of a class that has a member whose type has a deleted destructor. If a member has a deleted destructor, then that member cannot be destroyed. If a member can't be destroyed, the object as a whole can't be destroyed.

Although we cannot define variables or members of such types, we can dynamically allocate objects with a deleted destructor. However, we cannot free them:

Click here to view code image

```
struct NoDtor {
    NoDtor() = default; // use the synthesized default constructor
    ~NoDtor() = delete; // we can't destroy objects of type NoDtor
};
NoDtor nd; // error: NoDtor destructor is deleted
NoDtor *p = new NoDtor(); // ok: but we can't delete p
delete p; // error: NoDtor destructor is deleted
```

Warning

It is not possible to define an object or delete a pointer to a dynamically allocated object of a type with a deleted destructor.

The Copy-Control Members May Be Synthesized as Deleted

As we've seen, if we do not define the copy-control members, the compiler defines them for us. Similarly, if a class defines no constructors, the compiler synthesizes a default constructor for that class (§ 7.1.4, p. 262). For some classes, the compiler defines these synthesized members as deleted functions:

- The synthesized destructor is defined as deleted if the class has a member whose own destructor is deleted or is inaccessible (e.g., private).
- The synthesized copy constructor is defined as deleted if the class has a member whose own copy constructor is deleted or inaccessible. It is also deleted

if the class has a member with a deleted or inaccessible destructor.

- The synthesized copy-assignment operator is defined as deleted if a member has a deleted or inaccessible copy-assignment operator, or if the class has a const or reference member.
- The synthesized default constructor is defined as deleted if the class has a member with a deleted or inaccessible destructor; or has a reference member that does not have an in-class initializer (§ 2.6.1, p. 73); or has a const member whose type does not explicitly define a default constructor and that member does not have an in-class initializer.

In essence, these rules mean that if a class has a data member that cannot be default constructed, copied, assigned, or destroyed, then the corresponding member will be a deleted function.

It may be surprising that a member that has a deleted or inaccessible destructor causes the synthesized default and copy constructors to be defined as deleted. The reason for this rule is that without it, we could create objects that we could not destroy.

It should not be surprising that the compiler will not synthesize a default constructor for a class with a reference member or a const member that cannot be default constructed. Nor should it be surprising that a class with a const member cannot use the synthesized copy-assignment operator: After all, that operator attempts to assign to every member. It is not possible to assign a new value to a const object.

Although we can assign a new value to a reference, doing so changes the value of the object to which the reference refers. If the copy-assignment operator were synthesized for such classes, the left-hand operand would continue to refer to the same object as it did before the assignment. It would not refer to the same object as the right-hand operand. Because this behavior is unlikely to be desired, the synthesized copy-assignment operator is defined as deleted if the class has a reference member.

We'll see in § 13.6.2 (p. 539), § 15.7.2 (p. 624), and § 19.6 (p. 849) that there are other aspects of a class that can cause its copy members to be defined as deleted.

In essence, the copy-control members are synthesized as deleted when it is impossible to copy, assign, or destroy a member of the class.

private Copy Control

Prior to the new standard, classes prevented copies by declaring their copy constructor and copy-assignment operator as private:

Click here to view code image

```
class PrivateCopy {
     // no access specifier; following members are private by default; see § 7.2 (p.
268)
     // copy control is private and so is inaccessible to ordinary user code
     PrivateCopy(const PrivateCopy&);
     PrivateCopy &operator=(const PrivateCopy&);
     // other members
public:
     PrivateCopy() = default; // use the synthesized default constructor
     ~PrivateCopy(); // users can define objects of this type but not copy them
};
```

Because the destructor is public, users will be able to define PrivateCopy objects. However, because the copy constructor and copy-assignment operator are private, user code will not be able to copy such objects. However, friends and members of the class can still make copies. To prevent copies by friends and members, we declare these members as private but do not define them.

With one exception, which we'll cover in § 15.2.1 (p. 594), it is legal to declare, but not define, a member function (§ 6.1.2, p. 206). An attempt to use an undefined member results in a link-time failure. By declaring (but not defining) a private copy constructor, we can forestall any attempt to copy an object of the class type: User code that tries to make a copy will be flagged as an error at compile time; copies made in member functions or friends will result in an error at link time.

Best Practices

Classes that want to prevent copying should define their copy constructor and copy-assignment operators using = delete rather than making those members private.

Exercises Section 13.1.6

Exercise 13.18: Define an Employee class that contains an employee name and a unique employee identifier. Give the class a default constructor and a constructor that takes a string representing the employee's name. Each constructor should generate a unique ID by incrementing a static data member.

Exercise 13.19: Does your Employee class need to define its own versions of the copy-control members? If so, why? If not, why not? Implement whatever copy-control members you think Employee needs.

Exercise 13.20: Explain what happens when we copy, assign, or destroy objects of our TextQuery and QueryResult classes from § 12.3 (p. 484).

Exercise 13.21: Do you think the TextQuery and QueryResult classes need to define their own versions of the copy-control members? If so, why? If not, why not? Implement whichever copy-control operations you think these classes require.

13.2. Copy Control and Resource Management

Ordinarily, classes that manage resources that do not reside in the class must define the copy-control members. As we saw in § 13.1.4 (p. 504), such classes will need destructors to free the resources allocated by the object. Once a class needs a destructor, it almost surely needs a copy constructor and copy-assignment operator as well.

In order to define these members, we first have to decide what copying an object of our type will mean. In general, we have two choices: We can define the copy operations to make the class behave like a value or like a pointer.

Classes that behave like values have their own state. When we copy a valuelike object, the copy and the original are independent of each other. Changes made to the copy have no effect on the original, and vice versa.

Classes that act like pointers share state. When we copy objects of such classes, the copy and the original use the same underlying data. Changes made to the copy also change the original, and vice versa.

Of the library classes we've used, the library containers and string class have valuelike behavior. Not surprisingly, the shared_ptr class provides pointerlike behavior, as does our StrBlob class (§ 12.1.1, p. 456). The IO types and unique_ptr do not allow copying or assignment, so they provide neither valuelike nor pointerlike behavior.

To illustrate these two approaches, we'll define the copy-control members for the HasPtr class used in the exercises. First, we'll make the class act like a value; then we'll reimplement the class making it behave like a pointer.

Our HasPtr class has two members, an int and a pointer to string. Ordinarily, classes copy members of built-in type (other than pointers) directly; such members are values and hence ordinarily ought to behave like values. What we do when we copy the pointer member determines whether a class like HasPtr has valuelike or pointerlike behavior.

Exercises Section 13.2

Exercise 13.22: Assume that we want HasPtr to behave like a value. That

is, each object should have its own copy of the string to which the objects point. We'll show the definitions of the copy-control members in the next section. However, you already know everything you need to know to implement these members. Write the HasPtr copy constructor and copy-assignment operator before reading on.

13.2.1. Classes That Act Like Values

To provide valuelike behavior, each object has to have its own copy of the resource that the class manages. That means each HasPtr object must have its own copy of the string to which ps points. To implement valuelike behavior HasPtr needs

- A copy constructor that copies the string, not just the pointer
- A destructor to free the string
- A copy-assignment operator to free the object's existing string and copy the string from its right-hand operand

The valuelike version of HasPtr is

Click here to view code image

```
class HasPtr {
public:
    HasPtr(const std::string &s = std::string()):
        ps(new std::string(s)), i(0) { }
    // each HasPtr has its own copy of the string to which ps points
    HasPtr(const HasPtr &p):
        ps(new std::string(*p.ps)), i(p.i) { }
    HasPtr& operator=(const HasPtr &);
    ~HasPtr() { delete ps; }
private:
    std::string *ps;
    int i;
};
```

Our class is simple enough that we've defined all but the assignment operator in the class body. The first constructor takes an (optional) string argument. That constructor dynamically allocates its own copy of that string and stores a pointer to that string in ps. The copy constructor also allocates its own, separate copy of the string. The destructor frees the memory allocated in its constructors by executing delete on the pointer member, ps.

Valuelike Copy-Assignment Operator

Assignment operators typically combine the actions of the destructor and the copy

constructor. Like the destructor, assignment destroys the left-hand operand's resources. Like the copy constructor, assignment copies data from the right-hand operand. However, it is crucially important that these actions be done in a sequence that is correct even if an object is assigned to itself. Moreover, when possible, we should also write our assignment operators so that they will leave the left-hand operand in a sensible state should an exception occur (§ 5.6.2, p. 196).

In this case, we can handle self-assignment—and make our code safe should an exception happen—by first copying the right-hand side. After the copy is made, we'll free the left-hand side and update the pointer to point to the newly allocated string:

Click here to view code image

```
HasPtr& HasPtr::operator=(const HasPtr &rhs)
{
    auto newp = new string(*rhs.ps); // copy the underlying string
    delete ps; // free the old memory
    ps = newp; // copy data from rhs into this object
    i = rhs.i;
    return *this; // return this object
}
```

In this assignment operator, we quite clearly first do the work of the constructor: The initializer of newp is identical to the initializer of ps in HasPtr's copy constructor. As in the destructor, we next delete the string to which ps currently points. What remains is to copy the pointer to the newly allocated string and the int value from rhs into this object.

Key Concept: Assignment Operators

There are two points to keep in mind when you write an assignment operator:

- Assignment operators must work correctly if an object is assigned to itself.
- Most assignment operators share work with the destructor and copy constructor.

A good pattern to use when you write an assignment operator is to first copy the right-hand operand into a local temporary. *After* the copy is done, it is safe to destroy the existing members of the left-hand operand. Once the left-hand operand is destroyed, copy the data from the temporary into the members of the left-hand operand.

To illustrate the importance of guarding against self-assignment, consider what would happen if we wrote the assignment operator as

If rhs and this object are the same object, deleting ps frees the string to which both *this and rhs point. When we attempt to copy * (rhs.ps) in the new expression, that pointer points to invalid memory. What happens is undefined.

It is crucially important for assignment operators to work correctly, even when an object is assigned to itself. A good way to do so is to copy the right-hand operand before destroying the left-hand operand.

Exercises Section 13.2.1

Exercise 13.23: Compare the copy-control members that you wrote for the solutions to the previous section's exercises to the code presented here. Be sure you understand the differences, if any, between your code and ours.

Exercise 13.24: What would happen if the version of HasPtr in this section didn't define a destructor? What if HasPtr didn't define the copy constructor?

Exercise 13.25: Assume we want to define a version of StrBlob that acts like a value. Also assume that we want to continue to use a shared_ptr so that our StrBlobPtr class can still use a weak_ptr to the vector. Your revised class will need a copy constructor and copy-assignment operator but will not need a destructor. Explain what the copy constructor and copy-assignment operators must do. Explain why the class does not need a destructor.

Exercise 13.26: Write your own version of the StrBlob class described in the previous exercise.

13.2.2. Defining Classes That Act Like Pointers

For our HasPtr class to act like a pointer, we need the copy constructor and copy-assignment operator to copy the pointer member, not the string to which that pointer points. Our class will still need its own destructor to free the memory allocated by the constructor that takes a string (§ 13.1.4, p. 504). In this case, though, the destructor cannot unilaterally free its associated string. It can do so only when the last HasPtr pointing to that string goes away.

The easiest way to make a class act like a pointer is to use shared_ptrs to
manage the resources in the class. Copying (or assigning) a shared_ptr copies
(assigns) the pointer to which the shared_ptr points. The shared_ptr class itself
keeps track of how many users are sharing the pointed-to object. When there are no
more users, the shared_ptr class takes care of freeing the resource.

However, sometimes we want to manage a resource directly. In such cases, it can be useful to use a **reference count** (§ 12.1.1, p. 452). To show how reference counting works, we'll redefine HasPtr to provide pointerlike behavior, but we will do our own reference counting.

Reference Counts

Reference counting works as follows:

- In addition to initializing the object, each constructor (other than the copy constructor) creates a counter. This counter will keep track of how many objects share state with the object we are creating. When we create an object, there is only one such object, so we initialize the counter to 1.
- The copy constructor does not allocate a new counter; instead, it copies the data members of its given object, including the counter. The copy constructor increments this shared counter, indicating that there is another user of that object's state.
- The destructor decrements the counter, indicating that there is one less user of the shared state. If the count goes to zero, the destructor deletes that state.
- The copy-assignment operator increments the right-hand operand's counter and decrements the counter of the left-hand operand. If the counter for the left-hand operand goes to zero, there are no more users. In this case, the copy-assignment operator must destroy the state of the left-hand operand.

The only wrinkle is deciding where to put the reference count. The counter cannot be a direct member of a HasPtr object. To see why, consider what happens in the following example:

```
HasPtr p1("Hiya!");
HasPtr p2(p1); // p1 and p2 point to the same string
HasPtr p3(p1); // p1, p2, and p3 all point to the same string
```

If the reference count is stored in each object, how can we update it correctly when p3 is created? We could increment the count in p1 and copy that count into p3, but how would we update the counter in p2?

One way to solve this problem is to store the counter in dynamic memory. When we create an object, we'll also allocate a new counter. When we copy or assign an object, we'll copy the pointer to the counter. That way the copy and the original will point to the same counter.

Defining a Reference-Counted Class

Using a reference count, we can write the pointerlike version of HasPtr as follows:

Click here to view code image

```
class HasPtr {
public:
    // constructor allocates a new string and a new counter, which it sets to 1
    HasPtr(const std::string &s = std::string()):
        ps(new std::string(s)), i(0), use(new std::size_t(1))
{ }
    // copy constructor copies all three data members and increments the counter
    HasPtr(const HasPtr &p):
         ps(p.ps), i(p.i), use(p.use) { ++*use; }
    HasPtr& operator=(const HasPtr&);
    ~HasPtr();
private:
    std::string *ps;
     std::size_t *use; // member to keep track of how many objects share
*ps
};
```

Here, we've added a new data member named use that will keep track of how many objects share the same string. The constructor that takes a string allocates this counter and initializes it to 1, indicating that there is one user of this object's string member.

Pointerlike Copy Members "Fiddle" the Reference Count

When we copy or assign a HasPtr object, we want the copy and the original to point to the same string. That is, when we copy a HasPtr, we'll copy ps itself, not the string to which ps points. When we make a copy, we also increment the counter associated with that string.

The copy constructor (which we defined inside the class) copies all three members from its given HasPtr. This constructor also increments the use member, indicating that there is another user for the string to which ps and p.ps point.

The destructor cannot unconditionally delete ps—there might be other objects pointing to that memory. Instead, the destructor decrements the reference count, indicating that one less object shares the string. If the counter goes to zero, then the destructor frees the memory to which both ps and use point:

Click here to view code image

The copy-assignment operator, as usual, does the work common to the copy constructor and to the destructor. That is, the assignment operator must increment the counter of the right-hand operand (i.e., the work of the copy constructor) and decrement the counter of the left-hand operand, deleting the memory used if appropriate (i.e., the work of the destructor).

Also, as usual, the operator must handle self-assignment. We do so by incrementing the count in rhs before decrementing the count in the left-hand object. That way if both objects are the same, the counter will have been incremented before we check to see if ps (and use) should be deleted:

Click here to view code image

Exercises Section 13.2.2

Exercise 13.27: Define your own reference-counted version of HasPtr.

Exercise 13.28: Given the following classes, implement a default constructor and the necessary copy-control members.

```
(a)
class TreeNode {
```

```
private:
    std::string value;
    int count;
    TreeNode *left;
    TreeNode *right;
};

(b)
class BinStrTree {
    private:
        TreeNode *root;
    };
```

13.3. Swap

In addition to defining the copy-control members, classes that manage resources often also define a function named swap (§ 9.2.5, p. 339). Defining swap is particularly important for classes that we plan to use with algorithms that reorder elements (§ 10.2.3, p. 383). Such algorithms call swap whenever they need to exchange two elements.

If a class defines its own swap, then the algorithm uses that class-specific version. Otherwise, it uses the swap function defined by the library. Although, as usual, we don't know how swap is implemented, conceptually it's easy to see that swapping two objects involves a copy and two assignments. For example, code to swap two objects of our valuelike HasPtr class (§ 13.2.1, p. 511) might look something like:

Click here to view code image

```
HasPtr temp = v1; // make a temporary copy of the value of v1
v1 = v2; // assign the value of v2 to v1
v2 = temp; // assign the saved value of v1 to v2
```

This code copies the string that was originally in v1 twice—once when the HasPtr copy constructor copies v1 into temp and again when the assignment operator assigns temp to v2. It also copies the string that was originally in v2 when it assigns v2 to v1. As we've seen, copying a valuelike HasPtr allocates a new string and copies the string to which the HasPtr points.

In principle, none of this memory allocation is necessary. Rather than allocating new copies of the string, we'd like swap to swap the pointers. That is, we'd like swapping two HasPtrs to execute as:

```
string *temp = v1.ps; // make a temporary copy of the pointer in v1.ps
v1.ps = v2.ps; // assign the pointer in v2.ps to v1.ps
```

```
// assign the saved pointer in v1.ps to v2.ps
v2.ps = temp;
```

Writing Our Own swap Function

We can override the default behavior of swap by defining a version of swap that operates on our class. The typical implementation of swap is:

Click here to view code image

```
class HasPtr {
    friend void swap(HasPtr&, HasPtr&);
    // other members as in § 13.2.1 (p. 511)
};
inline
void swap(HasPtr &lhs, HasPtr &rhs)
    using std::swap;
    swap(lhs.ps, rhs.ps); // swap the pointers, not the string data
    swap(lhs.i, rhs.i); // swap the int members
```

We start by declaring swap as a friend to give it access to HasPtr's (private) data members. Because swap exists to optimize our code, we've defined swap as an inline function (§ 6.5.2, p. 238). The body of swap calls swap on each of the data members of the given object. In this case, we first swap the pointers and then the int members of the objects bound to rhs and lhs.

Unlike the copy-control members, swap is never necessary. However, defining swap can be an important optimization for classes that allocate resources.

swap Functions Should Call swap, Not std::swap

There is one important subtlety in this code: Although it doesn't matter in this particular case, it is essential that swap functions call swap and not std::swap. In the HasPtr function, the data members have built-in types. There is no type-specific version of swap for the built-in types. In this case, these calls will invoke the library std::swap.

However, if a class has a member that has its own type-specific swap function, calling std::swap would be a mistake. For example, assume we had another class named Foo that has a member named h, which has type HasPtr. If we did not write a Foo version of swap, then the library version of swap would be used. As we've already seen, the library swap makes unnecessary copies of the strings managed by HasPtr.

We can avoid these copies by writing a swap function for Foo. However, if we wrote the Foo version of swap as:

Click here to view code image

```
void swap(Foo &lhs, Foo &rhs)
{
    // WRONG: this function uses the library version of swap, not the HasPtr
version
    std::swap(lhs.h, rhs.h);
    // swap other members of type Foo
}
```

this code would compile and execute. However, there would be no performance difference between this code and simply using the default version of swap. The problem is that we've explicitly requested the library version of swap. However, we don't want the version in std; we want the one defined for HasPtr objects.

The right way to write this swap function is:

Click here to view code image

```
void swap(Foo &lhs, Foo &rhs)
{
    using std::swap;
    swap(lhs.h, rhs.h); // uses the HasPtr version of swap
    // swap other members of type Foo
}
```

Each call to swap must be unqualified. That is, each call should be to swap, not std::swap. For reasons we'll explain in § 16.3 (p. 697), if there is a type-specific version of swap, that version will be a better match than the one defined in std. As a result, if there is a type-specific version of swap, calls to swap will match that type-specific version. If there is no type-specific version, then—assuming there is a using declaration for swap in scope—calls to swap will use the version in std.

Very careful readers may wonder why the using declaration inside swap does not hide the declarations for the HasPtr version of swap (§ 6.4.1, p. 234). We'll explain the reasons for why this code works in § 18.2.3 (p. 798).

Using swap in Assignment Operators

Classes that define swap often use swap to define their assignment operator. These operators use a technique known as **copy and swap**. This technique swaps the left-hand operand with a *copy* of the right-hand operand:

Click here to view code image

```
// note rhs is passed by value, which means the HasPtr copy constructor
// copies the string in the right-hand operand into rhs
HasPtr& HasPtr::operator=(HasPtr rhs)
{
    // swap the contents of the left-hand operand with the local variable rhs
    swap(*this, rhs); // rhs now points to the memory this object had used
    return *this; // rhs is destroyed, which deletes the pointer in rhs
}
```

In this version of the assignment operator, the parameter is not a reference. Instead, we pass the right-hand operand by value. Thus, rhs is a copy of the right-hand operand. Copying a HasPtr allocates a new copy of that object's string.

In the body of the assignment operator, we call <code>swap</code>, which swaps the data members of <code>rhs</code> with those in *this. This call puts the pointer that had been in the left-hand operand into <code>rhs</code>, and puts the pointer that was in <code>rhs</code> into *this. Thus, after the <code>swap</code>, the pointer member in *this points to the newly allocated <code>string</code> that is a copy of the right-hand operand.

When the assignment operator finishes, rhs is destroyed and the HasPtr destructor is run. That destructor deletes the memory to which rhs now points, thus freeing the memory to which the left-hand operand had pointed.

The interesting thing about this technique is that it automatically handles self assignment and is automatically exception safe. By copying the right-hand operand before changing the left-hand operand, it handles self assignment in the same was as we did in our original assignment operator (§ 13.2.1, p. 512). It manages exception safety in the same way as the original definition as well. The only code that might throw is the new expression inside the copy constructor. If an exception occurs, it will happen before we have changed the left-hand operand.

Tip

Assignment operators that use copy and swap are automatically exception safe and correctly handle self-assignment.

Exercises Section 13.3

Exercise 13.29: Explain why the calls to swap inside swap(HasPtr&, HasPtr&) do not cause a recursion loop.

Exercise 13.30: Write and test a swap function for your valuelike version of HasPtr. Give your swap a print statement that notes when it is executed.

Exercise 13.31: Give your class a < operator and define a vector of HasPtrs. Give that vector some elements and then sort the vector.

Note when swap is called.

Exercise 13.32: Would the pointerlike version of HasPtr benefit from defining a swap function? If so, what is the benefit? If not, why not?

13.4. A Copy-Control Example

Although copy control is most often needed for classes that allocate resources, resource management is not the only reason why a class might need to define these members. Some classes have bookkeeping or other actions that the copy-control members must perform.

As an example of a class that needs copy control in order to do some bookkeeping, we'll sketch out two classes that might be used in a mail-handling application. These classes, Message and Folder, represent, respectively, email (or other kinds of) messages, and directories in which a message might appear. Each Message can appear in multiple Folders. However, there will be only one copy of the contents of any given Message. That way, if the contents of a Message are changed, those changes will appear when we view that Message from any of its Folders.

To keep track of which Messages are in which Folders, each Message will store a set of pointers to the Folders in which it appears, and each Folder will contain a set of pointers to its Messages. Figure 13.1 illustrates this design.

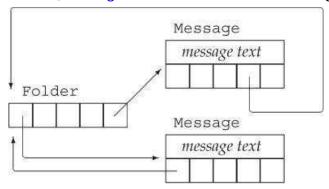

Figure 13.1. Message and Folder Class Design

Our Message class will provide save and remove operations to add or remove a Message from a specified Folder. To create a new Message, we will specify the contents of the message but no Folder. To put a Message in a particular Folder, we must call save.

When we copy a Message, the copy and the original will be distinct Messages, but both Messages should appear in the same set of Folders. Thus, copying a Message will copy the contents and the set of Folder pointers. It must also add a pointer to the newly created Message to each of those Folders.

When we destroy a Message, that Message no longer exists. Therefore, destroying

a Message must remove pointers to that Message from the Folders that had contained that Message.

When we assign one Message to another, we'll replace the contents of the lefthand Message with those in the right-hand side. We must also update the set of Folders, removing the left-hand Message from its previous Folders and adding that Message to the Folders in which the right-hand Message appears.

Looking at this list of operations, we can see that both the destructor and the copyassignment operator have to remove this Message from the Folders that point to it. Similarly, both the copy constructor and the copy-assignment operator add a Message to a given list of Folders. We'll define a pair of private utility functions to do these tasks.

Best Practices

The copy-assignment operator often does the same work as is needed in the copy constructor and destructor. In such cases, the common work should be put in private utility functions.

The Folder class will need analogous copy control members to add or remove itself from the Messages it stores.

We'll leave the design and implementation of the Folder class as an exercise. However, we'll assume that the Folder class has members named addMsg and remMsg that do whatever work is need to add or remove this Message, respectively, from the set of messages in the given Folder.

The Message Class

Given this design, we can write our Message class as follows:

```
class Message {
     friend class Folder;
public:
     // folders is implicitly initialized to the empty set
     explicit Message(const std::string &str = ""):
          contents(str) { }
     // copy control to manage pointers to this Message
    Message(const Message&);
                                                // copy constructor
    Message& operator=(const Message&); // copy assignment
     ~Message();
                                                // destructor
     // add/remove this Message from the specified Folder's set of messages
     void save(Folder&);
     void remove(Folder&);
```

The class defines two data members: contents, to store the message text, and folders, to store pointers to the Folders in which this Message appears. The constructor that takes a string copies the given string into contents and (implicitly) initializes folders to the empty set. Because this constructor has a default argument, it is also the Message default constructor (§ 7.5.1, p. 290).

The save and remove Members

Aside from copy control, the Message class has only two public members: save, which puts the Message in the given Folder, and remove, which takes it out:

Click here to view code image

```
void Message::save(Folder &f)
{
    folders.insert(&f); // add the given Folder to our list of Folders
    f.addMsg(this); // add this Message to f's set of Messages
}
void Message::remove(Folder &f)
{
    folders.erase(&f); // take the given Folder out of our list of Folders
    f.remMsg(this); // remove this Message to f's set of Messages
}
```

To save (or remove) a Message requires updating the folders member of the Message. When we save a Message, we store a pointer to the given Folder; when we remove a Message, we remove that pointer.

These operations must also update the given Folder. Updating a Folder is a job that the Folder class controls through its addMsg and remMsg members, which will add or remove a pointer to a given Message, respectively.

Copy Control for the Message Class

When we copy a Message, the copy should appear in the same Folders as the original Message. As a result, we must traverse the set of Folder pointers adding a pointer to the new Message to each Folder that points to the original Message. Both the copy constructor and the copy-assignment operator will need to do this work,

so we'll define a function to do this common processing:

Click here to view code image

```
// add this Message to Folders that point to m
void Message::add_to_Folders(const Message &m)
{
   for (auto f : m.folders) // for each Folder that holds m
        f->addMsg(this); // add a pointer to this Message to that Folder
}
```

Here we call addMsg on each Folder in m.folders. The addMsg function will add a pointer to this Message to that Folder.

The Message copy constructor copies the data members of the given object:

Click here to view code image

```
Message::Message(const Message &m):
        contents(m.contents), folders(m.folders)
{
        add_to_Folders(m); // add this Message to the Folders that point to m
}
```

and calls add_to_Folders to add a pointer to the newly created Message to each Folder that contains the original Message.

The Message Destructor

When a Message is destroyed, we must remove this Message from the Folders that point to it. This work is shared with the copy-assignment operator, so we'll define a common function to do it:

Click here to view code image

The implementation of the remove_from_Folders function is similar to that of add_to_Folders, except that it uses remMsg to remove the current Message.

Given the remove_from_Folders function, writing the destructor is trivial:

```
Message::~Message()
{
    remove_from_Folders();
```

}

The call to remove_from_Folders ensures that no Folder has a pointer to the Message we are destroying. The compiler automatically invokes the string destructor to free contents and the set destructor to clean up the memory used by those members.

Message Copy-Assignment Operator

In common with most assignment operators, our Folder copy-assignment operator must do the work of the copy constructor and the destructor. As usual, it is crucial that we structure our code to execute correctly even if the left- and right-hand operands happen to be the same object.

In this case, we protect against self-assignment by removing pointers to this Message from the folders of the left-hand operand before inserting pointers in the folders in the right-hand operand:

Click here to view code image

```
Message& Message::operator=(const Message &rhs)
{
    // handle self-assignment by removing pointers before inserting them
    remove_from_Folders();    // update existing Folders
    contents = rhs.contents;    // copy message contents from rhs
    folders = rhs.folders;    // copy Folder pointers from rhs
    add_to_Folders(rhs);    // add this Message to those Folders
    return *this;
}
```

If the left- and right-hand operands are the same object, then they have the same address. Had we called remove_from_folders after calling add_to_folders, we would have removed this Message from all of its corresponding Folders.

A swap Function for Message

The library defines versions of swap for both string and set (§ 9.2.5, p. 339). As a result, our Message class will benefit from defining its own version of swap. By defining a Message-specific version of swap, we can avoid extraneous copies of the contents and folders members.

However, our swap function must also manage the Folder pointers that point to the swapped Messages. After a call such as swap(m1, m2), the Folders that had pointed to m1 must now point to m2, and vice versa.

We'll manage the Folder pointers by making two passes through each of the folders members. The first pass will remove the Messages from their respective Folders. We'll next call swap to swap the data members. We'll make the second

pass through folders this time adding pointers to the swapped Messages:

Click here to view code image

```
void swap(Message &lhs, Message &rhs)
    using std::swap; // not strictly needed in this case, but good habit
     // remove pointers to each Message from their (original) respective Folders
    for (auto f: lhs.folders)
         f->remMsq(&lhs);
    for (auto f: rhs.folders)
         f->remMsg(&rhs);
     // swap the contents and Folder pointer sets
     swap(lhs.folders, rhs.folders);
                                               // uses swap(set&, set&)
    swap(lhs.contents, rhs.contents);
                                               // swap(string&, string&)
     // add pointers to each Message to their (new) respective Folders
    for (auto f: lhs.folders)
         f->addMsq(&lhs);
    for (auto f: rhs.folders)
         f->addMsq(&rhs);
}
```

Exercises Section 13.4

Exercise 13.33: Why is the parameter to the save and remove members of Message a Folder&? Why didn't we define that parameter as Folder? Or const Folder&?

Exercise 13.34: Write the Message class as described in this section.

Exercise 13.35: What would happen if Message used the synthesized versions of the copy-control members?

Exercise 13.36: Design and implement the corresponding Folder class. That class should hold a set that points to the Messages in that Folder.

Exercise 13.37: Add members to the Message class to insert or remove a given Folder* into folders. These members are analogous to Folder's addMsg and remMsg operations.

Exercise 13.38: We did not use copy and swap to define the Message assignment operator. Why do you suppose this is so?

13.5. Classes That Manage Dynamic Memory

Some classes need to allocate a varying amount of storage at run time. Such classes often can (and if they can, generally should) use a library container to hold their data. For example, our StrBlob class uses a vector to manage the underlying storage for

its elements.

However, this strategy does not work for every class; some classes need to do their own allocation. Such classes generally must define their own copy-control members to manage the memory they allocate.

As an example, we'll implement a simplification of the library vector class. Among the simplifications we'll make is that our class will not be a template. Instead, our class will hold strings. Thus, we'll call our class StrVec.

StrVec Class Design

Recall that the vector class stores its elements in contiguous storage. To obtain acceptable performance, vector preallocates enough storage to hold more elements than are needed (§ 9.4, p. 355). Each vector member that adds elements checks whether there is space available for another element. If so, the member constructs an object in the next available spot. If there isn't space left, then the vector is reallocated: The vector obtains new space, moves the existing elements into that space, frees the old space, and adds the new element.

We'll use a similar strategy in our StrVec class. We'll use an allocator to obtain raw memory (§ 12.2.2, p. 481). Because the memory an allocator allocates is unconstructed, we'll use the allocator's construct member to create objects in that space when we need to add an element. Similarly, when we remove an element, we'll use the destroy member to destroy the element.

Each StrVec will have three pointers into the space it uses for its elements:

- elements, which points to the first element in the allocated memory
- first_free, which points just after the last actual element
- cap, which points just past the end of the allocated memory

Figure 13.2 illustrates the meaning of these pointers.

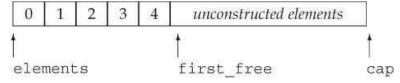

Figure 13.2. StrVec Memory Allocation Strategy

In addition to these pointers, StrVec will have a member named alloc that is an allocator<string>. The alloc member will allocate the memory used by a StrVec. Our class will also have four utility functions:

- alloc_n_copy will allocate space and copy a given range of elements.
- free will destroy the constructed elements and deallocate the space.
- chk_n_alloc will ensure that there is room to add at least one more element

to the StrVec. If there isn't room for another element, chk_n_alloc will call reallocate to get more space.

• reallocate will reallocate the StrVec when it runs out of space.

Although our focus is on the implementation, we'll also define a few members from vector's interface.

StrVec Class Definition

Having sketched the implementation, we can now define our StrVec class:

Click here to view code image

```
// simplified implementation of the memory allocation strategy for a vector-like class
class StrVec {
public:
     StrVec(): // the allocator member is default initialized
        elements(nullptr), first_free(nullptr), cap(nullptr) {
}
     StrVec(const StrVec&);
                                               // copy constructor
     StrVec & operator = (const StrVec&); // copy assignment
     ~StrVec();
                                               // destructor
     void push_back(const std::string&); // copy the element
     size_t size() const { return first_free - elements; }
     size_t capacity() const { return cap - elements; }
     std::string *begin() const { return elements;
std::string *end() const { return first_free;
     // ...
private:
     std::allocator<std::string> alloc; // allocates the elements
     // used by the functions that add elements to the StrVec
     void chk n alloc()
          { if (size() == capacity()) reallocate(); }
     // utilities used by the copy constructor, assignment operator, and destructor
     std::pair<std::string*, std::string*> alloc_n_copy
          (const std::string*, const std::string*);
     void free();
                                   // destroy the elements and free the space
     void reallocate();
                                    // get more space and copy the existing
elements
     std::string *elements;
                                   // pointer to the first element in the array
     std::string *first_free; // pointer to the first free element in the array
                                   // pointer to one past the end of the array
     std::string *cap;
};
```

The class body defines several of its members:

• The default constructor (implicitly) default initializes alloc and (explicitly) initializes the pointers to nullptr, indicating that there are no elements.

- The size member returns the number of elements actually in use, which is equal to first_free elements.
- The capacity member returns the number of elements that the StrVec can hold, which is equal to cap elements.
- The chk_n_alloc causes the StrVec to be reallocated when there is no room to add another element, which happens when cap == first_free.
- The begin and end members return pointers to the first (i.e., elements) and one past the last constructed element (i.e., first_free), respectively.

Using construct

The push_back function calls chk_n_alloc to ensure that there is room for an element. If necessary, chk_n_alloc will call reallocate. When chk_n_alloc returns, push_back knows that there is room for the new element. It asks its allocator member to construct a new last element:

Click here to view code image

```
void StrVec::push_back(const string& s)
{
    chk_n_alloc(); // ensure that there is room for another element
    // construct a copy of s in the element to which first_free points
    alloc.construct(first_free++, s);
}
```

When we use an allocator to allocate memory, we must remember that the memory is unconstructed (§ 12.2.2, p. 482). To use this raw memory we must call construct, which will construct an object in that memory. The first argument to construct must be a pointer to unconstructed space allocated by a call to allocate. The remaining arguments determine which constructor to use to construct the object that will go in that space. In this case, there is only one additional argument. That argument has type string, so this call uses the string copy constructor.

It is worth noting that the call to construct also increments first_free to indicate that a new element has been constructed. It uses the postfix increment (§ 4.5, p. 147), so this call constructs an object in the current value of first_free and increments first_free to point to the next, unconstructed element.

The alloc_n_copy Member

The alloc_n_copy member is called when we copy or assign a StrVec. Our StrVec class, like vector, will have valuelike behavior (§ 13.2.1, p. 511); when we copy or assign a StrVec, we have to allocate independent memory and copy the elements from the original to the new StrVec.

The alloc_n_copy member will allocate enough storage to hold its given range of elements, and will copy those elements into the newly allocated space. This function returns a pair (§ 11.2.3, p. 426) of pointers, pointing to the beginning of the new space and just past the last element it copied:

Click here to view code image

```
pair<string*, string*>
StrVec::alloc_n_copy(const string *b, const string *e)
{
    // allocate space to hold as many elements as are in the range
    auto data = alloc.allocate(e - b);
    // initialize and return a pair constructed from data and
    // the value returned by uninitialized_copy
    return {data, uninitialized_copy(b, e, data)};
}
```

alloc_n_copy calculates how much space to allocate by subtracting the pointer to the first element from the pointer one past the last. Having allocated memory, the function next has to construct copies of the given elements in that space.

It does the copy in the return statement, which list initializes the return value (§ 6.3.2, p. 226). The first member of the returned pair points to the start of the allocated memory; the second is the value returned from uninitialized_copy (§ 12.2.2, p. 483). That value will be pointer positioned one element past the last constructed element.

The free Member

The free member has two responsibilities: It must destroy the elements and then deallocate the space that this StrVec itself allocated. The for loop calls the allocator member destroy in reverse order, starting with the last constructed element and finishing with the first:

Click here to view code image

```
void StrVec::free()
{
    // may not pass deallocate a 0 pointer; if elements is 0, there's no work to do
    if (elements) {
        // destroy the old elements in reverse order
        for (auto p = first_free; p != elements; /* empty */)
            alloc.destroy(--p);
        alloc.deallocate(elements, cap - elements);
    }
}
```

The destroy function runs the string destructor. The string destructor frees whatever storage was allocated by the strings themselves.

Once the elements have been destroyed, we free the space that this StrVec allocated by calling deallocate. The pointer we pass to deallocate must be one that was previously generated by a call to allocate. Therefore, we first check that elements is not null before calling deallocate.

Copy-Control Members

Given our alloc_n_copy and free members, the copy-control members of our class are straightforward. The copy constructor calls alloc_n_copy:

Click here to view code image

```
StrVec::StrVec(const StrVec &s)
{
    // call alloc_n_copy to allocate exactly as many elements as in s
    auto newdata = alloc_n_copy(s.begin(), s.end());
    elements = newdata.first;
    first_free = cap = newdata.second;
}
```

and assigns the results from that call to the data members. The return value from alloc_n_copy is a pair of pointers. The first pointer points to the first constructed element and the second points just past the last constructed element. Because alloc_n_copy allocates space for exactly as many elements as it is given, cap also points just past the last constructed element.

The destructor calls free:

Click here to view code image

```
StrVec::~StrVec() { free(); }
```

The copy-assignment operator calls alloc_n_copy before freeing its existing elements. By doing so it protects against self-assignment:

Click here to view code image

```
StrVec &StrVec::operator=(const StrVec &rhs)
{
    // call alloc_n_copy to allocate exactly as many elements as in rhs
    auto data = alloc_n_copy(rhs.begin(), rhs.end());
    free();
    elements = data.first;
    first_free = cap = data.second;
    return *this;
}
```

Like the copy constructor, the copy-assignment operator uses the values returned from alloc n copy to initialize its pointers.

Moving, Not Copying, Elements during Reallocation

Before we write the reallocate member, we should think a bit about what it must do. This function will

- Allocate memory for a new, larger array of strings
- Construct the first part of that space to hold the existing elements
- Destroy the elements in the existing memory and deallocate that memory

Looking at this list of steps, we can see that reallocating a StrVec entails copying each string from the old StrVec memory to the new. Although we don't know the details of how string is implemented, we do know that strings have valuelike behavior. When we copy a string, the new string and the original string are independent from each other. Changes made to the original don't affect the copy, and vice versa.

Because strings act like values, we can conclude that each string must have its own copy of the characters that make up that string. Copying a string must allocate memory for those characters, and destroying a string must free the memory used by that string.

Copying a string copies the data because ordinarily after we copy a string, there are two users of that string. However, when reallocate copies the strings in a StrVec, there will be only one user of these strings after the copy. As soon as we copy the elements from the old space to the new, we will immediately destroy the original strings.

Copying the data in these strings is unnecessary. Our StrVec's performance will be *much* better if we can avoid the overhead of allocating and deallocating the strings themselves each time we reallocate.

Move Constructors and std::move

We can avoid copying the strings by using two facilities introduced by the new library. First, several of the library classes, including string, define so-called "move constructors." The details of how the string move constructor works—like any other detail about the implementation—are not disclosed. However, we do know that move constructors typically operate by "moving" resources from the given object to the object being constructed. We also know that the library guarantees that the "moved-from" string remains in a valid, destructible state. For string, we can imagine that each string has a pointer to an array of char. Presumably the string move constructor copies the pointer rather than allocating space for and copying the characters themselves.

The second facility we'll use is a library function named **move**, which is defined in the utility header. For now, there are two important points to know about move.

First, for reasons we'll explain in § 13.6.1 (p. 532), when reallocate constructs the strings in the new memory it must call move to signal that it wants to use the string move constructor. If it omits the call to move the string the copy constructor will be used. Second, for reasons we'll cover in § 18.2.3 (p. 798), we usually do not provide a using declaration (§ 3.1, p. 82) for move. When we use move, we call std::move, not move.

The reallocate Member

Using this information, we can now write our reallocate member. We'll start by calling allocate to allocate new space. We'll double the capacity of the StrVec each time we reallocate. If the StrVec is empty, we allocate room for one element:

Click here to view code image

```
void StrVec::reallocate()
      // we'll allocate space for twice as many elements as the current size
      auto newcapacity = size() ? 2 * size() : 1;
      // allocate new memory
      auto newdata = alloc.allocate(newcapacity);
      // move the data from the old memory to the new
       auto dest = newdata; // points to the next free position in the new
array
      auto elem = elements; // points to the next element in the old array
      for (size t i = 0; i != size(); ++i)
           alloc.construct(dest++, std::move(*elem++));
      free(); // free the old space once we've moved the elements
      // update our data structure to point to the new elements
      elements = newdata;
      first_free = dest;
      cap = elements + newcapacity;
```

The for loop iterates through the existing elements and constructs a corresponding element in the new space. We use dest to point to the memory in which to construct the new string, and use elem to point to an element in the original array. We use postfix increment to move the dest (and elem) pointers one element at a time through these two arrays.

The second argument in the call to <code>construct</code> (i.e., the one that determines which constructor to use (§ 12.2.2, p. 482)) is the value returned by <code>move</code>. Calling <code>move</code> returns a result that causes <code>construct</code> to use the <code>string</code> move constructor. Because we're using the move constructor, the memory managed by those <code>strings</code> will not be copied. Instead, each <code>string</code> we construct will take over ownership of the memory from the <code>string</code> to which <code>elem</code> points.

After moving the elements, we call free to destroy the old elements and free the

memory that this StrVec was using before the call to reallocate. The strings themselves no longer manage the memory to which they had pointed; responsibility for their data has been moved to the elements in the new StrVec memory. We don't know what value the strings in the old StrVec memory have, but we are quaranteed that it is safe to run the string destructor on these objects.

What remains is to update the pointers to address the newly allocated and initialized array. The first_free and cap pointers are set to denote one past the last constructed element and one past the end of the allocated space, respectively.

Exercises Section 13.5

Exercise 13.39: Write your own version of StrVec, including versions of reserve, capacity (§ 9.4, p. 356), and resize (§ 9.3.5, p. 352).

Exercise 13.40: Add a constructor that takes an initializer_list<string> to your StrVec class.

Exercise 13.41: Why did we use postfix increment in the call to construct inside push_back? What would happen if it used the prefix increment?

Exercise 13.42: Test your StrVec class by using it in place of the vector<string> in your TextQuery and QueryResult classes (§ 12.3, p. 484).

Exercise 13.43: Rewrite the free member to use for_each and a lambda (§ 10.3.2, p. 388) in place of the for loop to destroy the elements. Which implementation do you prefer, and why?

Exercise 13.44: Write a class named String that is a simplified version of the library string class. Your class should have at least a default constructor and a constructor that takes a pointer to a C-style string. Use an allocator to allocate memory that your String class uses.

13.6. Moving Objects

One of the major features in the new standard is the ability to move rather than copy an object. As we saw in § 13.1.1 (p. 497), copies are made in many circumstances. In some of these circumstances, an object is immediately destroyed after it is copied. In those cases, moving, rather than copying, the object can provide a significant performance boost.

As we've just seen, our StrVec class is a good example of this kind of superfluous copy. During reallocation, there is no need to copy—rather than move—the elements from the old memory to the new. A second reason to move rather than copy occurs in classes such as the IO or unique_ptr classes. These classes have a resource (such

as a pointer or an IO buffer) that may not be shared. Hence, objects of these types can't be copied but can be moved.

Under earlier versions of the language, there was no direct way to move an object. We had to make a copy even if there was no need for the copy. If the objects are large, or if the objects themselves require memory allocation (e.g., strings), making a needless copy can be expensive. Similarly, in previous versions of the library, classes stored in a container had to be copyable. Under the new standard, we can use containers on types that cannot be copied so long as they can be moved.

The library containers, string, and shared_ptr classes support move as well as copy. The IO and unique_ptr classes can be moved but not copied.

13.6.1. Rvalue References

To support move operations, the new standard introduced a new kind of reference, an rvalue reference. An rvalue reference is a reference that must be bound to an rvalue. An rvalue reference is obtained by using && rather than &. As we'll see, rvalue references have the important property that they may be bound only to an object that is about to be destroyed. As a result, we are free to "move" resources from an rvalue reference to another object.

Recall that Ivalue and rvalue are properties of an expression (§ 4.1.1, p. 135). Some expressions yield or require Ivalues; others yield or require rvalues. Generally speaking, an Ivalue expression refers to an object's identity whereas an rvalue expression refers to an object's value.

Like any reference, an rvalue reference is just another name for an object. As we know, we cannot bind regular references—which we'll refer to as **Ivalue references** when we need to distinguish them from rvalue references—to expressions that require a conversion, to literals, or to expressions that return an rvalue (§ 2.3.1, p. 51). Rvalue references have the opposite binding properties: We can bind an rvalue reference to these kinds of expressions, but we cannot directly bind an rvalue reference to an Ivalue:

```
int i = 42i
int &r = i;
                             // ok: r refers to i
                               // error: cannot bind an rvalue reference to an
int \&\&rr = i;
lvalue
```

```
int &r2 = i * 42; // error: i*42 is an rvalue
const int &r3 = i * 42; // ok: we can bind a reference to const to an
rvalue
int \&\&rr2 = i * 42;
                            // ok: bind rr2 to the result of the multiplication
```

Functions that return Ivalue references, along with the assignment, subscript, dereference, and prefix increment/decrement operators, are all examples of expressions that return Ivalues. We can bind an Ivalue reference to the result of any of these expressions.

Functions that return a nonreference type, along with the arithmetic, relational, bitwise, and postfix increment/decrement operators, all yield rvalues. We cannot bind an Ivalue reference to these expressions, but we can bind either an Ivalue reference to const or an rvalue reference to such expressions.

Lvalues Persist; Rvalues Are Ephemeral

Looking at the list of Ivalue and rvalue expressions, it should be clear that Ivalues and rvalues differ from each other in an important manner: Lvalues have persistent state, whereas rvalues are either literals or temporary objects created in the course of evaluating expressions.

Because rvalue references can only be bound to temporaries, we know that

- The referred-to object is about to be destroyed
- There can be no other users of that object

These facts together mean that code that uses an rvalue reference is free to take over resources from the object to which the reference refers.

Rvalue references refer to objects that are about to be destroyed. Hence, we can "steal" state from an object bound to an rvalue reference.

Variables Are Lyalues

Although we rarely think about it this way, a variable is an expression with one operand and no operator. Like any other expression, a variable expression has the Ivalue/rvalue property. Variable expressions are Ivalues. It may be surprising, but as a consequence, we cannot bind an rvalue reference to a variable defined as an rvalue reference type:

```
// ok: literals are rvalues
int \&\&rr1 = 42;
int &&rr2 = rr1; // error: the expression rrl is an lvalue!
```

Given our previous observation that rvalues represent ephemeral objects, it should not be surprising that a variable is an Ivalue. After all, a variable persists until it goes out of scope.

Note

A variable is an Ivalue; we cannot directly bind an rvalue reference to a variable even if that variable was defined as an rvalue reference type.

The Library move Function

Although we cannot directly bind an rvalue reference to an Ivalue, we can explicitly cast an Ivalue to its corresponding rvalue reference type. We can also obtain an rvalue reference bound to an Ivalue by calling a new library function named move, which is defined in the utility header. The move function uses facilities that we'll describe in § 16.2.6 (p. 690) to return an rvalue reference to its given object.

Click here to view code image

```
int &&rr3 = std::move(rr1); // ok
```

Calling move tells the compiler that we have an Ivalue that we want to treat as if it were an rvalue. It is essential to realize that the call to move promises that we do not intend to use rr1 again except to assign to it or to destroy it. After a call to move, we cannot make any assumptions about the value of the moved-from object.

Note

We can destroy a moved-from object and can assign a new value to it, but we cannot use the value of a moved-from object.

As we've seen, differently from how we use most names from the library, we do not provide a using declaration (§ 3.1, p. 82) for move (§ 13.5, p. 530). We call std::move not move. We'll explain the reasons for this usage in § 18.2.3 (p. 798).

Warning

Code that uses move should use std::move, not move. Doing so avoids potential name collisions.

Exercises Section 13.6.1

Exercise 13.45: Distinguish between an rvalue reference and an Ivalue reference.

Exercise 13.46: Which kind of reference can be bound to the following initializers?

```
int f();
vector<int> vi(100);
int? r1 = f();
int? r2 = vi[0];
int? r3 = r1;
int? r4 = vi[0] * f();
```

Exercise 13.47: Give the copy constructor and copy-assignment operator in your String class from exercise 13.44 in § 13.5 (p. 531) a statement that prints a message each time the function is executed.

Exercise 13.48: Define a vector<String> and call push_back several times on that vector. Run your program and see how often Strings are copied.

13.6.2. Move Constructor and Move Assignment

Like the string class (and other library classes), our own classes can benefit from being able to be moved as well as copied. To enable move operations for our own types, we define a move constructor and a move-assignment operator. These members are similar to the corresponding copy operations, but they "steal" resources from their given object rather than copy them.

Like the copy constructor, the move constructor has an initial parameter that is a reference to the class type. Differently from the copy constructor, the reference parameter in the move constructor is an rvalue reference. As in the copy constructor, any additional parameters must all have default arguments.

In addition to moving resources, the move constructor must ensure that the moved-from object is left in a state such that destroying that object will be harmless. In particular, once its resources are moved, the original object must no longer point to those moved resources—responsibility for those resources has been assumed by the newly created object.

As an example, we'll define the StrVec move constructor to move rather than copy

the elements from one StrVec to another:

Click here to view code image

We'll explain the use of noexcept (which signals that our constructor does not throw any exceptions) shortly, but let's first look at what this constructor does.

Unlike the copy constructor, the move constructor does not allocate any new memory; it takes over the memory in the given <code>StrVec</code>. Having taken over the memory from its argument, the constructor body sets the pointers in the given object to <code>nullptr</code>. After an object is moved from, that object continues to exist. Eventually, the moved-from object will be destroyed, meaning that the destructor will be run on that object. The <code>StrVec</code> destructor calls <code>deallocate</code> on <code>first_free</code>. If we neglected to change <code>s.first_free</code>, then destroying the moved-from object would delete the memory we just moved.

Move Operations, Library Containers, and Exceptions

Because a move operation executes by "stealing" resources, it ordinarily does not itself allocate any resources. As a result, move operations ordinarily will not throw any exceptions. When we write a move operation that cannot throw, we should inform the library of that fact. As we'll see, unless the library knows that our move constructor won't throw, it will do extra work to cater to the possibliity that moving an object of our class type might throw.

One way inform the library is to specify noexcept on our constructor. We'll cover noexcept, which was introduced by the new standard, in more detail in § 18.1.4 (p. 779). For now what's important to know is that noexcept is a way for us to promise that a function does not throw any exceptions. We specify noexcept on a function after its parameter list. In a constructor, noexcept appears between the parameter list and the: that begins the constructor initializer list:

```
class StrVec {
public:
```

```
StrVec(StrVec&&) noexcept;  // move constructor
    // other members as before
};
StrVec::StrVec(StrVec &&s) noexcept: /* member initializers */
{    /* constructor body    */ }
```

We must specify noexcept on both the declaration in the class header and on the definition if that definition appears outside the class.

Note

Move constructors and move assignment operators that cannot throw exceptions should be marked as noexcept.

Understanding why noexcept is needed can help deepen our understanding of how the library interacts with objects of the types we write. We need to indicate that a move operation doesn't throw because of two interrelated facts: First, although move operations usually don't throw exceptions, they are permitted to do so. Second, the library containers provide guarantees as to what they do if an exception happens. As one example, vector guarantees that if an exception happens when we call push_back, the vector itself will be left unchanged.

Now let's think about what happens inside <code>push_back</code>. Like the corresponding <code>StrVec</code> operation (§ 13.5, p. 527), <code>push_back</code> on a vector might require that the vector be reallocated. When a vector is reallocated, it moves the elements from its old space to new memory, just as we did in reallocate (§ 13.5, p. 530).

As we've just seen, moving an object generally changes the value of the moved-from object. If reallocation uses a move constructor and that constructor throws an exception after moving some but not all of the elements, there would be a problem. The moved-from elements in the old space would have been changed, and the unconstructed elements in the new space would not yet exist. In this case, vector would be unable to meet its requirement that the vector is left unchanged.

On the other hand, if vector uses the copy constructor and an exception happens, it can easily meet this requirement. In this case, while the elements are being constructed in the new memory, the old elements remain unchanged. If an exception happens, vector can free the space it allocated (but could not successfully construct) and return. The original vector elements still exist.

To avoid this potential problem, vector must use a copy constructor instead of a move constructor during reallocation unless it knows that the element type's move constructor cannot throw an exception. If we want objects of our type to be moved rather than copied in circumstances such as vector reallocation, we must explicity tell the library that our move constructor is safe to use. We do so by marking the move constructor (and move-assignment operator) noexcept.

Move-Assignment Operator

The move-assignment operator does the same work as the destructor and the move constructor. As with the move constructor, if our move-assignment operator won't throw any exceptions, we should make it noexcept. Like a copy-assignment operator, a move-assignment operator must guard against self-assignment:

Click here to view code image

In this case we check directly whether the this pointer and the address of rhs are the same. If they are, the right- and left-hand operands refer to the same object and there is no work to do. Otherwise, we free the memory that the left-hand operand had used, and then take over the memory from the given object. As in the move constructor, we set the pointers in rhs to nullptr.

It may seem surprising that we bother to check for self-assignment. After all, move assignment requires an rvalue for the right-hand operand. We do the check because that rvalue could be the result of calling move. As in any other assignment operator, it is crucial that we not free the left-hand resources before using those (possibly same) resources from the right-hand operand.

A Moved-from Object Must Be Destructible

Moving from an object does not destroy that object: Sometime after the move operation completes, the moved-from object will be destroyed. Therefore, when we write a move operation, we must ensure that the moved-from object is in a state in which the destructor can be run. Our StrVec move operations meet this requirement by setting the pointer members of the moved-from object to nullptr.

In addition to leaving the moved-from object in a state that is safe to destroy, move operations must guarantee that the object remains valid. In general, a valid object is one that can safely be given a new value or used in other ways that do not depend

on its current value. On the other hand, move operations have no requirements as to the value that remains in the moved-from object. As a result, our programs should never depend on the value of a moved-from object.

For example, when we move from a library string or container object, we know that the moved-from object remains valid. As a result, we can run operations such as as empty or size on moved-from objects. However, we don't know what result we'll get. We might expect a moved-from object to be empty, but that is not guaranteed.

Our Strvec move operations leave the moved-from object in the same state as a default-initialized object. Therefore, all the operations of StrVec will continue to run the same way as they do for any other default-initialized StrVec. Other classes, with more complicated internal structure, may behave differently.

Warning

After a move operation, the "moved-from" object must remain a valid, destructible object but users may make no assumptions about its value.

The Synthesized Move Operations

As it does for the copy constructor and copy-assignment operator, the compiler will synthesize the move constructor and move-assignment operator. However, the conditions under which it synthesizes a move operation are quite different from those in which it synthesizes a copy operation.

Recall that if we do not declare our own copy constructor or copy-assignment operator the compiler always synthesizes these operations (§ 13.1.1, p. 497 and § 13.1.2, p. 500). The copy operations are defined either to memberwise copy or assign the object or they are defined as deleted functions.

Differently from the copy operations, for some classes the compiler does not synthesize the move operations at all. In particular, if a class defines its own copy constructor, copy-assignment operator, or destructor, the move constructor and moveassignment operator are not synthesized. As a result, some classes do not have a move constructor or a move-assignment operator. As we'll see on page 540, when a class doesn't have a move operation, the corresponding copy operation is used in place of move through normal function matching.

The compiler will synthesize a move constructor or a move-assignment operator only if the class doesn't define any of its own copy-control members and if every nonstatic data member of the class can be moved. The compiler can move members of built-in type. It can also move members of a class type if the member's class has the corresponding move operation:

Note

The compiler synthesizes the move constructor and move assignment only if a class does not define any of its own copy-control members and only if all the data members can be moved constructed and move assigned, respectively.

Unlike the copy operations, a move operation is never implicitly defined as a deleted function. However, if we explicitly ask the compiler to generate a move operation by using = default (§ 7.1.4, p. 264), and the compiler is unable to move all the members, then the move operation will be defined as deleted. With one important exception, the rules for when a synthesized move operation is defined as deleted are analogous to those for the copy operations (§ 13.1.6, p. 508):

- Unlike the copy constructor, the move constructor is defined as deleted if the class has a member that defines its own copy constructor but does not also define a move constructor, or if the class has a member that doesn't define its own copy operations and for which the compiler is unable to synthesize a move constructor. Similarly for move-assignment.
- The move constructor or move-assignment operator is defined as deleted if the class has a member whose own move constructor or move-assignment operator is deleted or inaccessible.
- Like the copy constructor, the move constructor is defined as deleted if the destructor is deleted or inaccessible.
- Like the copy-assignment operator, the move-assignment operator is defined as deleted if the class has a const or reference member.

For example, assuming Y is a class that defines its own copy constructor but does not also define its own move constructor:

Click here to view code image

// assume Y is a class that defines its own copy constructor but not a move constructor

```
struct hasY {
    hasY() = default;
    hasY(hasY&&) = default;
    Y mem; // hasY will have a deleted move constructor
};
hasY hy, hy2 = std::move(hy); // error: move constructor is deleted
```

The compiler can copy objects of type Y but cannot move them. Class hasY explicitly requested a move constructor, which the compiler is unable to generate. Hence, hasY will get a deleted move constructor. Had hasY omitted the declaration of its move constructor, then the compiler would not synthesize the hasY move constructor at all. The move operations are not synthesized if they would otherwise be defined as deleted.

There is one final interaction between move operations and the synthesized copycontrol members: Whether a class defines its own move operations has an impact on how the copy operations are synthesized. If the class defines either a move constructor and/or a move-assignment operator, then the synthesized copy constructor and copy-assignment operator for that class will be defined as deleted.

Note

Classes that define a move constructor or move-assignment operator must also define their own copy operations. Otherwise, those members are deleted by default.

Rvalues Are Moved, Lvalues Are Copied ...

When a class has both a move constructor and a copy constructor, the compiler uses ordinary function matching to determine which constructor to use (§ 6.4, p. 233). Similarly for assignment. For example, in our StrVec class the copy versions take a reference to const StrVec. As a result, they can be used on any type that can be converted to StrVec. The move versions take a StrVec& and can be used only when the argument is a (nonconst) rvalue:

Click here to view code image

In the first assignment, we pass v2 to the assignment operator. The type of v2 is StrVec and the expression, v2, is an Ivalue. The move version of assignment is not viable (§ 6.6, p. 243), because we cannot implicitly bind an rvalue reference to an Ivalue. Hence, this assignment uses the copy-assignment operator.

In the second assignment, we assign from the result of a call to getVec. That expression is an rvalue. In this case, both assignment operators are viable—we can bind the result of getVec to either operator's parameter. Calling the copy-assignment operator requires a conversion to const, whereas StrVec&& is an exact match. Hence, the second assignment uses the move-assignment operator.

... But Rvalues Are Copied If There Is No Move Constructor

What if a class has a copy constructor but does not define a move constructor? In this case, the compiler will not synthesize the move constructor, which means the class has a copy constructor but no move constructor. If a class has no move constructor, function matching ensures that objects of that type are copied, even if we attempt to move them by calling move:

Click here to view code image

```
class Foo {
public:
     Foo() = default;
     Foo(const Foo&); // copy constructor
     // other members, but Foo does not define a move constructor
};
Foo x;
Foo y(x);
                          // copy constructor; x is an lvalue
Foo z(std::move(x)); // copy constructor, because there is no move constructor
```

The call to move(x) in the initialization of z returns a Foo&& bound to x. The copy constructor for Foo is viable because we can convert a Foo&& to a const Foo&. Thus, the initialization of z uses the copy constructor for Foo.

It is worth noting that using the copy constructor in place of a move constructor is almost surely safe (and similarly for the assignment operators). Ordinarily, the copy constructor will meet the requirements of the corresponding move constructor: It will copy the given object and leave that original object in a valid state. Indeed, the copy constructor won't even change the value of the original object.

If a class has a usable copy constructor and no move constructor, objects will be "moved" by the copy constructor. Similarly for the copy-assignment operator and move-assignment.

Copy-and-Swap Assignment Operators and Move

The version of our HasPtr class that defined a copy-and-swap assignment operator

(§ 13.3, p. 518) is a good illustration of the interaction between function matching and move operations. If we add a move constructor to this class, it will effectively get a move assignment operator as well:

Click here to view code image

In this version of the class, we've added a move constructor that takes over the values from its given argument. The constructor body sets the pointer member of the given HasPtr to zero to ensure that it is safe to destroy the moved-from object. Nothing this function does can throw an exception so we mark it as noexcept (§ 13.6.2, p. 535).

Now let's look at the assignment operator. That operator has a nonreference parameter, which means the parameter is copy initialized (§ 13.1.1, p. 497). Depending on the type of the argument, copy initialization uses either the copy constructor or the move constructor; Ivalues are copied and rvalues are moved. As a result, this single assignment operator acts as both the copy-assignment and move-assignment operator.

For example, assuming both hp and hp2 are HasPtr objects:

Click here to view code image

```
hp = hp2; // hp2 is an lvalue; copy constructor used to copy hp2
hp = std::move(hp2); // move constructor moves hp2
```

In the first assignment, the right-hand operand is an Ivalue, so the move constructor is not viable. The copy constructor will be used to initialize rhs. The copy constructor will allocate a new string and copy the string to which hp2 points.

In the second assignment, we invoke std:move to bind an rvalue reference to hp2. In this case, both the copy constructor and the move constructor are viable. However, because the argument is an rvalue reference, it is an exact match for the move constructor. The move constructor copies the pointer from hp2. It does not allocate any memory.

Regardless of whether the copy or move constructor was used, the body of the assignment operator swaps the state of the two operands. Swapping a HasPtr exchanges the pointer (and int) members of the two objects. After the swap, rhs will hold a pointer to the string that had been owned by the left-hand side. That

string will be destroyed when rhs goes out of scope.

Advice: Updating the Rule of Three

All five copy-control members should be thought of as a unit: Ordinarily, if a class defines any of these operations, it usually should define them all. As we've seen, some classes *must* define the copy constructor, copy-assignment operator, and destructor to work correctly (§ 13.1.4, p. 504). Such classes typically have a resource that the copy members must copy. Ordinarily, copying a resource entails some amount of overhead. Classes that define the move constructor and move-assignment operator can avoid this overhead in those circumstances where a copy isn't necessary.

Move Operations for the Message Class

Classes that define their own copy constructor and copy-assignment operator generally also benefit by defining the move operations. For example, our Message and Folder classes (§ 13.4, p. 519) should define move operations. By defining move operations, the Message class can use the string and set move operations to avoid the overhead of copying the contents and folders members.

However, in addition to moving the folders member, we must also update each Folder that points to the original Message. We must remove pointers to the old Message and add a pointer to the new one.

Both the move constructor and move-assignment operator need to update the Folder pointers, so we'll start by defining an operation to do this common work:

Click here to view code image

```
// move the Folder pointers from m to this Message
void Message::move_Folders(Message *m)
{
    folders = std::move(m->folders); // uses set move assignment
    for (auto f : folders) { // for each Folder
        f->remMsg(m); // remove the old Message from the Folder
        f->addMsg(this); // add this Message to that Folder
    }
    m->folders.clear(); // ensure that destroying m is harmless
}
```

This function begins by moving the folders set. By calling move, we use the set move assignment rather than its copy assignment. Had we omitted the call to move, the code would still work, but the copy is unnecessary. The function then iterates through those Folders, removing the pointer to the original Message and adding a pointer to the new Message.

It is worth noting that inserting an element to a set might throw an exception—adding an element to a container requires memory to be allocated, which means that a bad_alloc exception might be thrown (§ 12.1.2, p. 460). As a result, unlike our HasPtr and StrVec move operations, the Message move constructor and move-assignment operators might throw exceptions. We will not mark them as noexcept (§ 13.6.2, p. 535).

The function ends by calling clear on m.folders. After the move, we know that m.folders is valid but have no idea what its contents are. Because the Message destructor iterates through folders, we want to be certain that the set is empty.

The Message move constructor calls move to move the contents and default initializes its folders member:

Click here to view code image

In the body of the constructor, we call move_Folders to remove the pointers to m and insert pointers to this Message.

The move-assignment operator does a direct check for self-assignment:

Click here to view code image

As with any assignment operator, the move-assignment operator must destroy the old state of the left-hand operand. In this case, destroying the left-hand operand requires that we remove pointers to this Message from the existing folders, which we do in the call to remove_from_Folders. Having removed itself from its Folders, we call move to move the contents from rhs to this object. What remains is to call move_Messages to update the Folder pointers.

Move Iterators

The reallocate member of StrVec (§ 13.5, p. 530) used a for loop to call construct to copy the elements from the old memory to the new. As an alternative

to writing that loop, it would be easier if we could call uninitialized_copy to construct the newly allocated space. However, uninitialized_copy does what it says: It copies the elements. There is no analogous library function to "move" objects into unconstructed memory.

Instead, the new library defines a **move iterator** adaptor (§ 10.4, p. 401). A move iterator adapts its given iterator by changing the behavior of the iterator's dereference operator. Ordinarily, an iterator dereference operator returns an Ivalue reference to the element. Unlike other iterators, the dereference operator of a move iterator yields an rvalue reference.

We transform an ordinary iterator to a move iterator by calling the library make_move_iterator function. This function takes an iterator and returns a move iterator.

All of the original iterator's other operations work as usual. Because these iterators support normal iterator operations, we can pass a pair of move iterators to an algorithm. In particular, we can pass move iterators to uninitialized_copy:

Click here to view code image

uninitialized_copy calls construct on each element in the input sequence to "copy" that element into the destination. That algorithm uses the iterator dereference operator to fetch elements from the input sequence. Because we passed move iterators, the dereference operator yields an rvalue reference, which means construct will use the move constructor to construct the elements.

It is worth noting that standard library makes no guarantees about which algorithms can be used with move iterators and which cannot. Because moving an object can obliterate the source, you should pass move iterators to algorithms only when you are *confident* that the algorithm does not access an element after it has assigned to that element or passed that element to a user-defined function.

Advice: Don't Be Too Quick to Move

Because a moved-from object has indeterminate state, calling std::move on an object is a dangerous operation. When we call move, we must be absolutely certain that there can be no other users of the moved-from object.

Judiciously used inside class code, move can offer significant performance benefits. Casually used in ordinary user code (as opposed to class implementation code), moving an object is more likely to lead to mysterious and hard-to-find bugs than to any improvement in the performance of the application.

Best Practices

Outside of class implementation code such as move constructors or move-assignment operators, use std::move only when you are certain that you need to do a move and that the move is guaranteed to be safe.

Exercises Section 13.6.2

Exercise 13.49: Add a move constructor and move-assignment operator to your StrVec, String, and Message classes.

Exercise 13.50: Put print statements in the move operations in your String class and rerun the program from exercise 13.48 in § 13.6.1 (p. 534) that used a vector<String> to see when the copies are avoided.

Exercise 13.51: Although unique_ptrs cannot be copied, in § 12.1.5 (p. 471) we wrote a clone function that returned a unique_ptr by value. Explain why that function is legal and how it works.

Exercise 13.52: Explain in detail what happens in the assignments of the HasPtr objects on page 541. In particular, describe step by step what happens to values of hp, hp2, and of the rhs parameter in the HasPtr assignment operator.

Exercise 13.53: As a matter of low-level efficiency, the HasPtr assignment operator is not ideal. Explain why. Implement a copy-assignment and moveassignment operator for HasPtr and compare the operations executed in your new move-assignment operator versus the copy-and-swap version.

Exercise 13.54: What would happen if we defined a HasPtr moveassignment operator but did not change the copy-and-swap operator? Write code to test your answer.

13.6.3. Rvalue References and Member Functions

Member functions other than constructors and assignment can benefit from providing both copy and move versions. Such move-enabled members typically use the same parameter pattern as the copy/move constructor and the assignment operators—one version takes an Ivalue reference to const, and the second takes an rvalue reference to nonconst.

For example, the library containers that define $push_back$ provide two versions: one that has an rvalue reference parameter and the other a const lvalue reference. Assuming x is the element type, these containers define:

Click here to view code image

```
void push_back(const X\&); // copy: binds to any kind of X void push_back(X\&\&); // move: binds only to modifiable rvalues of type X
```

We can pass any object that can be converted to type x to the first version of push_back. This version copies data from its parameter. We can pass only an rvalue that is not const to the second version. This version is an exact match (and a better match) for nonconst rvalues and will be run when we pass a modifiable rvalue (§ 13.6.2, p. 539). This version is free to steal resources from its parameter.

Ordinarily, there is no need to define versions of the operation that take a const x&& or a (plain) x&. Usually, we pass an rvalue reference when we want to "steal" from the argument. In order to do so, the argument must not be const. Similarly, copying from an object should not change the object being copied. As a result, there is usually no need to define a version that take a (plain) x& parameter.

Note

Overloaded functions that distinguish between moving and copying a parameter typically have one version that takes a const T& and one that takes a T&&.

As a more concrete example, we'll give our StrVec class a second version of push_back:

```
class StrVec {
public:
    void push_back(const std::string&); // copy the element
    void push_back(std::string&&); // move the element
```

```
// other members as before
};

// unchanged from the original version in § 13.5 (p. 527)
void StrVec::push_back(const string& s)
{
    chk_n_alloc(); // ensure that there is room for another element
    // construct a copy of s in the element to which first_free points
    alloc.construct(first_free++, s);
}
void StrVec::push_back(string &&s)
{
    chk_n_alloc(); // reallocates the StrVec if necessary
    alloc.construct(first_free++, std::move(s));
}
```

These members are nearly identical. The difference is that the rvalue reference version of push_back calls move to pass its parameter to construct. As we've seen, the construct function uses the type of its second and subsequent arguments to determine which constructor to use. Because move returns an rvalue reference, the type of the argument to construct is string&&. Therefore, the string move constructor will be used to construct a new last element.

When we call push_back the type of the argument determines whether the new element is copied or moved into the container:

Click here to view code image

```
StrVec vec; // empty StrVec
string s = "some string or another";
vec.push_back(s); // calls push_back(const string&)
vec.push_back("done"); // calls push_back(string&&)
```

These calls differ as to whether the argument is an Ivalue (s) or an rvalue (the temporary string created from "done"). The calls are resolved accordingly.

Rvalue and Lvalue Reference Member Functions

Ordinarily, we can call a member function on an object, regardless of whether that object is an Ivalue or an rvalue. For example:

Click here to view code image

```
string s1 = "a value", s2 = "another";
auto n = (s1 + s2).find('a');
```

Here, we called the find member (§ 9.5.3, p. 364) on the string rvalue that results from adding two strings. Sometimes such usage can be surprising:

```
s1 + s2 = "wow!";
```

Here we assign to the rvalue result of concatentating these strings.

Prior to the new standard, there was no way to prevent such usage. In order to maintain backward compatability, the library classes continue to allow assignment to rvalues, However, we might want to prevent such usage in our own classes. In this case, we'd like to force the left-hand operand (i.e., the object to which this points) to be an Ivalue.

We indicate the Ivalue/rvalue property of this in the same way that we define const member functions (§ 7.1.2, p. 258); we place a **reference qualifier** after the parameter list:

Click here to view code image

```
class Foo {
public:
        Foo &operator=(const Foo&) &; // may assign only to modifiable

lvalues

        // other members of Foo
};
Foo &Foo::operator=(const Foo &rhs) &
{
        // do whatever is needed to assign rhs to this object
        return *this;
}
```

The reference qualifier can be either & or &&, indicating that this may point to an rvalue or Ivalue, respectively. Like the const qualifier, a reference qualifier may appear only on a (nonstatic) member function and must appear in both the declaration and definition of the function.

We may run a function qualified by & only on an Ivalue and may run a function qualified by && only on an rvalue:

Click here to view code image

```
Foo &retVal(); // returns a reference; a call to retVoo is an Ivalue
Foo retVal(); // returns by value; a call to retVal is an rvalue
Foo i, j; // i and j are Ivalues
i = j; // ok: i is an Ivalue
retFoo() = j; // ok: retFoo() returns an Ivalue
retVal() = j; // error: retVal() returns an rvalue
i = retVal(); // ok: we can pass an rvalue as the right-hand operand to assignment
```

A function can be both const and reference qualified. In such cases, the reference qualifier must follow the const qualifier:

```
class Foo {
```

Overloading and Reference Functions

Just as we can overload a member function based on whether it is const (§ 7.3.2, p. 276), we can also overload a function based on its reference qualifier. Moreover, we may overload a function by its reference qualifier and by whether it is a const member. As an example, we'll give Foo a vector member and a function named sorted that returns a copy of the Foo object in which the vector is sorted:

Click here to view code image

```
class Foo {
public:
    Foo sorted() &&;
                                   // may run on modifiable rvalues
                                   // may run on any kind of Foo
     Foo sorted() const &;
    // other members of Foo
private:
     vector<int> data;
// this object is an rvalue, so we can sort in place
Foo Foo::sorted() &&
     sort(data.begin(), data.end());
     return *this;
// this object is either const or it is an lyalue; either way we can't sort in place
Foo Foo::sorted() const & {
    Foo ret(*this);
                                                     // make a copy
     sort(ret.data.begin(), ret.data.end()); // sort the copy
     return ret;
                                                      // return the copy
}
```

When we run sorted on an rvalue, it is safe to sort the data member directly. The object is an rvalue, which means it has no other users, so we can change the object itself. When we run sorted on a const rvalue or on an Ivalue, we can't change this object, so we copy data before sorting it.

Overload resolution uses the Ivalue/rvalue property of the object that calls sorted to determine which version is used:

```
retVal().sorted(); // retVal() is an rvalue, calls Foo::sorted() && retFoo().sorted(); // retFoo() is an lvalue, calls Foo::sorted() const &
```

When we define const member functions, we can define two versions that differ only in that one is const qualified and the other is not. There is no similar default for reference qualified functions. When we define two or more members that have the same name and the same parameter list, we must provide a reference qualifier on all or none of those functions:

Click here to view code image

```
class Foo {
public:
    Foo sorted() &&;
    Foo sorted() const; // error: must have reference qualifier
    // Comp is type alias for the function type (see § 6.7 (p. 249))
    // that can be used to compare int values
    using Comp = bool(const int&, const int&);
    Foo sorted(Comp*); // ok: different parameter list
    Foo sorted(Comp*) const; // ok: neither version is reference qualified
};
```

Here the declaration of the const version of sorted that has no parameters is an error. There is a second version of sorted that has no parameters and that function has a reference qualifier, so the const version of that function must have a reference qualifier as well. On the other hand, the versions of sorted that take a pointer to a comparison operation are fine, because neither function has a qualifier.

Note

If a member function has a reference qualifier, all the versions of that member with the same parameter list must have reference qualifiers.

Exercises Section 13.6.3

Exercise 13.55: Add an rvalue reference version of push_back to your StrBlob.

Exercise 13.56: What would happen if we defined sorted as:

Click here to view code image

```
Foo Foo::sorted() const & {
    Foo ret(*this);
    return ret.sorted();
}
```

Exercise 13.57: What if we defined sorted as:

```
Foo Foo::sorted() const & { return Foo(*this).sorted(); }
```

Exercise 13.58: Write versions of class Foo with print statements in their sorted functions to test your answers to the previous two exercises.

Chapter Summary

Each class controls what happens when we copy, move, assign, or destroy objects of its type. Special member functions—the copy constructor, move constructor, copyassignment operator, move-assignment operator, and destructor—define these operations. The move constructor and move-assignment operator take a (usually nonconst) rvalue reference; the copy versions take a (usually const) ordinary lvalue reference.

If a class declares none of these operations, the compiler will define them automatically. If not defined as deleted, these operations memberwise initialize, move, assign, or destroy the object: Taking each nonstatic data member in turn, the synthesized operation does whatever is appropriate to the member's type to move, copy, assign, or destroy that member.

Classes that allocate memory or other resources almost always require that the class define the copy-control members to manage the allocated resource. If a class needs a destructor, then it almost surely needs to define the move and copy constructors and the move- and copy-assignment operators as well.

Defined Terms

copy and swap Technique for writing assignment operators by copying the right-hand operand followed by a call to swap to exchange the copy with the left-hand operand.

copy-assignment operator Version of the assignment operator that takes an object of the same type as its type. Ordinarily, the copy-assignment operator has a parameter that is a reference to const and returns a reference to its object. The compiler synthesizes the copy-assignment operator if the class does not explicitly provide one.

copy constructor Constructor that initializes a new object as a copy of another object of the same type. The copy constructor is applied implicitly to pass objects to or from a function by value. If we do not provide the copy constructor, the compiler synthesizes one for us.

copy control Special members that control what happens when objects of class type are copied, moved, assigned, and destroyed. The compiler synthesizes

appropriate definitions for these operations if the class does not otherwise declare them.

copy initialization Form of initialization used when we use = to supply an initializer for a newly created object. Also used when we pass or return an object by value and when we initialize an array or an aggregate class. Copy initialization uses the copy constructor or the move constructor, depending on whether the initializer is an Ivalue or an rvalue.

deleted function Function that may not be used. We delete a function by specifying = delete on its declaration. A common use of deleted functions is to tell the compiler not to synthesize the copy and/or move operations for a class.

destructor Special member function that cleans up an object when the object goes out of scope or is deleted. The compiler automatically destroys each data member. Members of class type are destroyed by invoking their destructor; no work is done when destroying members of built-in or compound type. In particular, the object pointed to by a pointer member is not deleted by the destructor.

Ivalue reference Reference that can bind to an Ivalue.

memberwise copy/assign How the synthesized copy and move constructors and the copy- and move-assignment operators work. Taking each nonstatic data member in turn, the synthesized copy or move constructor initializes each member by copying or moving the corresponding member from the given object; the copy- or move-assignment operators copy-assign or move-assign each member from the right-hand object to the left. Members of built-in or compound type are initialized or assigned directly. Members of class type are initialized or assigned by using the member's corresponding copy/move constructor or copy-/move-assignment operator.

move Library function used to bind an rvalue reference to an Ivalue. Calling move implicitly promises that we will not use the moved-from object except to destroy it or assign a new value to it.

move-assignment operator Version of the assignment operator that takes an rvalue reference to its type. Typically, a move-assignment operator moves data from the right-hand operand to the left. After the assignment, it must be safe to run the destructor on the right-hand operand.

move constructor Constructor that takes an rvalue reference to its type. Typically, a move constructor moves data from its parameter into the newly created object. After the move, it must be safe to run the destructor on the given argument.

move iterator Iterator adaptor that generates an iterator that, when dereferenced, yields an rvalue reference.

overloaded operator Function that redefines the meaning of an operator when applied to operand(s) of class type. This chapter showed how to define the assignment operator; Chapter 14 covers overloaded operators in more detail.

reference count Programming technique often used in copy-control members. A reference count keeps track of how many objects share state. Constructors (other than copy/move constructors) set the reference count to 1. Each time a new copy is made the count is incremented. When an object is destroyed, the count is decremented. The assignment operator and the destructor check whether the decremented reference count has gone to zero and, if so, they destroy the object.

reference qualifier Symbol used to indicate that a nonstatic member function can be called on an Ivalue or an rvalue. The qualifier, & or &&, follows the parameter list or the const qualifier if there is one. A function qualified by & may be called only on Ivalues; a function qualified by && may be called only on rvalues.

rvalue reference Reference to an object that is about to be destroyed.

synthesized assignment operator A version of the copy- or move-assignment operator created (synthesized) by the compiler for classes that do not explicitly define assignment operators. Unless it is defined as deleted, a synthesized assignment operator memberwise assigns (moves) the right-hand operand to the left.

synthesized copy/move constructor A version of the copy or move constructor that is generated by the compiler for classes that do not explicitly define the corresponding constructor. Unless it is defined as deleted, a synthesized copy or move constructor memberwise initializes the new object by copying or moving members from the given object, respectively.

synthesized destructor Version of the destructor created (synthesized) by the compiler for classes that do not explicitly define one. The synthesized destructor has an empty function body.

Chapter Summary

Defined Terms

In Chapter 4, we saw that C++ defines a large number of operators and automatic conversions among the built-in types. These facilities allow programmers to write a rich set of mixed-type expressions.

C++ lets us define what the operators mean when applied to objects of class type. It also lets us define conversions for class types. Class-type conversions are used like the built-in conversions to implicitly convert an object of one type to another type when needed.

Operator overloading lets us define the meaning of an operator when applied to operand(s) of a class type. Judicious use of operator overloading can make our programs easier to write and easier to read. As an example, because our original Sales_item class type (§ 1.5.1, p. 20) defined the input, output, and addition operators, we can print the sum of two Sales_items as

Click here to view code image

```
cout << item1 + item2; // print the sum of two Sales_items</pre>
```

In contrast, because our Sales_data class (§ 7.1, p. 254) does not yet have overloaded operators, code to print their sum is more verbose and, hence, less clear:

Click here to view code image

```
print(cout, add(data1, data2)); // print the sum of two Sales_datas
```

14.1. Basic Concepts

Overloaded operators are functions with special names: the keyword operator followed by the symbol for the operator being defined. Like any other function, an overloaded operator has a return type, a parameter list, and a body.

An overloaded operator function has the same number of parameters as the operator has operands. A unary operator has one parameter; a binary operator has two. In a binary operator, the left-hand operand is passed to the first parameter and

the right-hand operand to the second. Except for the overloaded function-call operator, operator(), an overloaded operator may not have default arguments (§ 6.5.1, p. 236).

If an operator function is a member function, the first (left-hand) operand is bound to the implicit this pointer (§ 7.1.2, p. 257). Because the first operand is implicitly bound to this, a member operator function has one less (explicit) parameter than the operator has operands.

Note

When an overloaded operator is a member function, this is bound to the left-hand operand. Member operator functions have one less (explicit) parameter than the number of operands.

An operator function must either be a member of a class or have at least one parameter of class type:

Click here to view code image

```
// error: cannot redefine the built-in operator for ints
int operator+(int, int);
```

This restriction means that we cannot change the meaning of an operator when applied to operands of built-in type.

We can overload most, but not all, of the operators. Table 14.1 shows whether or not an operator may be overloaded. We'll cover overloading new and delete in § 19.1.1 (p. 820).

Table 14.1. Operators

```
Operators That May Be Overloaded
                1
                            ++
        ==
                ! =
                            8.8
>>
        /=
                용=
                            \Pi
                                        ()
        <<=
                >>=
                new []
                            delete
                                        delete []
     Operators That Cannot Be Overloaded
                            ?:
::
```

We can overload only existing operators and cannot invent new operator symbols. For example, we cannot define operator** to provide exponentiation.

Four symbols (+, -, *, and &) serve as both unary and binary operators. Either or both of these operators can be overloaded. The number of parameters determines

which operator is being defined.

An overloaded operator has the same precedence and associativity (§ 4.1.2, p. 136) as the corresponding built-in operator. Regardless of the operand types

```
x == y + z;
is always equivalent to x == (y + z).
```

Calling an Overloaded Operator Function Directly

Ordinarily, we "call" an overloaded operator function indirectly by using the operator on arguments of the appropriate type. However, we can also call an overloaded operator function directly in the same way that we call an ordinary function. We name the function and pass an appropriate number of arguments of the appropriate type:

Click here to view code image

These calls are equivalent: Both call the nonmember function operator+, passing data1 as the first argument and data2 as the second.

We call a member operator function explicitly in the same way that we call any other member function. We name an object (or pointer) on which to run the function and use the dot (or arrow) operator to fetch the function we wish to call:

Click here to view code image

Each of these statements calls the member function operator+=, binding this to the address of data1 and passing data2 as an argument.

Some Operators Shouldn't Be Overloaded

Recall that a few operators guarantee the order in which operands are evaluated. Because using an overloaded operator is really a function call, these guarantees do not apply to overloaded operators. In particular, the operand-evaluation guarantees of the logical AND, logical OR (§ 4.3, p. 141), and comma (§ 4.10, p. 157) operators are not preserved. Moreover, overloaded versions of && or || operators do not preserve short-circuit evaluation properties of the built-in operators. Both operands are always evaluated.

Because the overloaded versions of these operators do not preserve order of

evaluation and/or short-circuit evaluation, it is usually a bad idea to overload them. Users are likely to be surprised when the evaluation guarantees they are accustomed to are not honored for code that happens to use an overloaded version of one of these operators.

Another reason not to overload comma, which also applies to the address-of operator, is that unlike most operators, the language defines what the comma and address-of operators mean when applied to objects of class type. Because these operators have built-in meaning, they ordinarily should not be overloaded. Users of the class will be surprised if these operators behave differently from their normal meanings.

Best Practices

Ordinarily, the comma, address-of, logical AND, and logical OR operators should *not* be overloaded.

Use Definitions That Are Consistent with the Built-in Meaning

When you design a class, you should always think first about what operations the class will provide. Only after you know what operations are needed should you think about whether to define each operation as an ordinary function or as an overloaded operator. Those operations with a logical mapping to an operator are good candidates for defining as overloaded operators:

- If the class does IO, define the shift operators to be consistent with how IO is done for the built-in types.
- If the class has an operation to test for equality, define operator==. If the class has operator == , it should usually have operator! = as well.
- If the class has a single, natural ordering operation, define operator<. If the class has operator<, it should probably have all of the relational operators.
- The return type of an overloaded operator usually should be compatible with the return from the built-in version of the operator: The logical and relational operators should return bool, the arithmetic operators should return a value of the class type, and assignment and compound assignment should return a reference to the left-hand operand.

Assignment and Compound Assignment Operators

Assignment operators should behave analogously to the synthesized operators: After an assignment, the values in the left-hand and right-hand operands should have the same value, and the operator should return a reference to its left-hand operand. Overloaded assignment should generalize the built-in meaning of assignment, not

circumvent it.

Caution: Use Operator Overloading Judiciously

Each operator has an associated meaning from its use on the built-in types. Binary +, for example, is strongly identified with addition. Mapping binary + to an analogous operation for a class type can provide a convenient notational shorthand. For example, the library string type, following a convention common to many programming languages, uses + to represent concatenation—"adding" one string to the other.

Operator overloading is most useful when there is a logical mapping of a built-in operator to an operation on our type. Using overloaded operators rather than inventing named operations can make our programs more natural and intuitive. Overuse or outright abuse of operator overloading can make our classes incomprehensible.

Obvious abuses of operator overloading rarely happen in practice. As an example, no responsible programmer would define <code>operator+</code> to perform subtraction. More common, but still inadvisable, are uses that contort an operator's "normal" meaning to force a fit to a given type. Operators should be used only for operations that are likely to be unambiguous to users. An operator has an ambiguous meaning if it plausibly has more than one interpretation.

If a class has an arithmetic (§ 4.2, p. 139) or bitwise (§ 4.8, p. 152) operator, then it is usually a good idea to provide the corresponding compound-assignment operator as well. Needless to say, the += operator should be defined to behave the same way the built-in operators do: it should behave as + followed by =.

Choosing Member or Nonmember Implementation

When we define an overloaded operator, we must decide whether to make the operator a class member or an ordinary nonmember function. In some cases, there is no choice—some operators are required to be members; in other cases, we may not be able to define the operator appropriately if it is a member.

The following guidelines can be of help in deciding whether to make an operator a member or an ordinary nonmember function:

- The assignment (=), subscript ([]), call (()), and member access arrow (->) operators *must* be defined as members.
- The compound-assignment operators ordinarily *ought* to be members. However, unlike assignment, they are not required to be members.
- Operators that change the state of their object or that are closely tied to their

given type—such as increment, decrement, and dereference—usually should be members.

• Symmetric operators—those that might convert either operand, such as the arithmetic, equality, relational, and bitwise operators—usually should be defined as ordinary nonmember functions.

Programmers expect to be able to use symmetric operators in expressions with mixed types. For example, we can add an int and a double. The addition is symmetric because we can use either type as the left-hand or the right-hand operand. If we want to provide similar mixed-type expressions involving class objects, then the operator must be defined as a nonmember function.

When we define an operator as a member function, then the left-hand operand must be an object of the class of which that operator is a member. For example:

Click here to view code image

```
string s = "world";
string t = s + "!"; // ok: we can add a const char* to a string
string u = "hi" + s; // would be an error if + were a member of string
```

If operator+ were a member of the string class, the first addition would be equivalent to s.operator+("!"). Likewise, "hi" + s would be equivalent to "hi".operator+(s). However, the type of "hi" is const char*, and that is a built-in type; it does not even have member functions.

Because string defines + as an ordinary nonmember function, "hi" + s is equivalent to operator+("hi", s). As with any function call, either of the arguments can be converted to the type of the parameter. The only requirements are that at least one of the operands has a class type, and that both operands can be converted (unambiguously) to string.

Exercises Section 14.1

Exercise 14.1: In what ways does an overloaded operator differ from a built-in operator? In what ways are overloaded operators the same as the built-in operators?

Exercise 14.2: Write declarations for the overloaded input, output, addition, and compound-assignment operators for Sales_data.

Exercise 14.3: Both string and vector define an overloaded == that can be used to compare objects of those types. Assuming svec1 and svec2 are vectors that hold strings, identify which version of == is applied in each of the following expressions:

```
(a) "cobble" == "stone"
```

(c) svec1 == svec2

(h)	"svec1[0]	l ==	"stone"
(u)	SVEGILU		\sim \sim \sim

Exercise 14.4: Explain how to decide whether the following should be class members:

- (a) %
- (b) %=
- (c) ++
- (d) ->
- (e) <<
- **(f)** &&
- (g) ==
- **(h)** ()

Exercise 14.5: In exercise 7.40 from § 7.5.1 (p. 291) you wrote a sketch of one of the following classes. Decide what, if any, overloaded operators your class should provide.

- (a) Book
- (b) Date
- (c) Employee
- (d) Vehicle
- (e) Object
- (f) Tree

14.2. Input and Output Operators

As we've seen, the IO library uses >> and << for input and output, respectively. The IO library itself defines versions of these operators to read and write the built-in types. Classes that support IO ordinarily define versions of these operators for objects of the class type.

14.2.1. Overloading the Output Operator <<

Ordinarily, the first parameter of an output operator is a reference to a nonconst ostream object. The ostream is nonconst because writing to the stream changes its state. The parameter is a reference because we cannot copy an ostream object.

The second parameter ordinarily should be a reference to const of the class type we want to print. The parameter is a reference to avoid copying the argument. It can be const because (ordinarily) printing an object does not change that object.

To be consistent with other output operators, operator<< normally returns its ostream parameter.

The Sales_data Output Operator

As an example, we'll write the Sales_data output operator:

Click here to view code image

```
ostream &operator<<(ostream &os, const Sales_data &item)</pre>
    os << item.isbn() << " " << item.units_sold << " "
       << item.revenue << " " << item.avg price();
    return os;
```

Except for its name, this function is identical to our earlier print function (§ 7.1.3, p. 261). Printing a Sales_data entails printing its three data elements and the computed average sales price. Each element is separated by a space. After printing the values, the operator returns a reference to the ostream it just wrote.

Output Operators Usually Do Minimal Formatting

The output operators for the built-in types do little if any formatting. In particular, they do not print newlines. Users expect class output operators to behave similarly. If the operator does print a newline, then users would be unable to print descriptive text along with the object on the same line. An output operator that does minimal formatting lets users control the details of their output.

Best Practices

Generally, output operators should print the contents of the object, with minimal formatting. They should not print a newline.

IO Operators Must Be Nonmember Functions

Input and output operators that conform to the conventions of the iostream library must be ordinary nonmember functions. These operators cannot be members of our own class. If they were, then the left-hand operand would have to be an object of our class type:

Click here to view code image

```
Sales_data data;
data << cout; // if operator<< is a member of Sales_data</pre>
```

If these operators are members of any class, they would have to be members of istream or ostream. However, those classes are part of the standard library, and we cannot add members to a class in the library.

Thus, if we want to define the IO operators for our types, we must define them as nonmember functions. Of course, IO operators usually need to read or write the nonpublic data members. As a consequence, IO operators usually must be declared as friends (§ 7.2.1, p. 269).

Exercises Section 14.2.1

Exercise 14.6: Define an output operator for your Sales_data class.

Exercise 14.7: Define an output operator for you String class you wrote for the exercises in § 13.5 (p. 531).

Exercise 14.8: Define an output operator for the class you chose in exercise 7.40 from § 7.5.1 (p. 291).

14.2.2. Overloading the Input Operator >>

Ordinarily the first parameter of an input operator is a reference to the stream from which it is to read, and the second parameter is a reference to the (nonconst) object into which to read. The operator usually returns a reference to its given stream. The second parameter must be nonconst because the purpose of an input operator is to read data into this object.

The Sales_data Input Operator

As an example, we'll write the Sales data input operator:

```
istream &operator>>(istream &is, Sales_data &item)
{
    double price; // no need to initialize; we'll read into price before we use
it
    is >> item.bookNo >> item.units_sold >> price;
    if (is) // check that the inputs succeeded
        item.revenue = item.units_sold * price;
    else
```

```
item = Sales_data(); // input failed: give the object the default
state
    return is;
}
```

Except for the if statement, this definition is similar to our earlier read function (§ 7.1.3, p. 261). The if checks whether the reads were successful. If an IO error occurs, the operator resets its given object to the empty Sales_data. That way, the object is guaranteed to be in a consistent state.

Note

Input operators must deal with the possibility that the input might fail; output operators generally don't bother.

Errors during Input

The kinds of errors that might happen in an input operator include the following:

- A read operation might fail because the stream contains data of an incorrect type. For example, after reading bookNo, the input operator assumes that the next two items will be numeric data. If nonnumeric data is input, that read and any subsequent use of the stream will fail.
- Any of the reads could hit end-of-file or some other error on the input stream.

Rather than checking each read, we check once after reading all the data and before using those data:

Click here to view code image

If any of the read operations fails, price will have an undefined value. Therefore, before using price, we check that the input stream is still valid. If it is, we do the calculation and store the result in revenue. If there was an error, we do not worry about which input failed. Instead, we reset the entire object to the empty Sales_data by assigning a new, default-initialized Sales_data object to item. After this assignment, item will have an empty string for its bookNo member, and its revenue and units_sold members will be zero.

Putting the object into a valid state is especially important if the object might have been partially changed before the error occurred. For example, in this input operator, we might encounter an error after successfully reading a new bookNo. An error after reading bookNo would mean that the units_sold and revenue members of the old

object were unchanged. The effect would be to associate a different bookno with those data.

By leaving the object in a valid state, we (somewhat) protect a user that ignores the possibility of an input error. The object will be in a usable state—its members are all defined. Similarly, the object won't generate misleading results—its data are internally consistent.

Best Practices

Input operators should decide what, if anything, to do about error recovery.

Indicating Errors

Some input operators need to do additional data verification. For example, our input operator might check that the bookNo we read is in an appropriate format. In such cases, the input operator might need to set the stream's condition state to indicate failure (§ 8.1.2, p. 312), even though technically speaking the actual IO was successful. Usually an input operator should set only the failbit. Setting eofbit would imply that the file was exhausted, and setting badbit would indicate that the stream was corrupted. These errors are best left to the IO library itself to indicate.

Exercises Section 14.2.2

Exercise 14.9: Define an input operator for your Sales data class.

Exercise 14.10: Describe the behavior of the Sales_data input operator if given the following input:

- (a) 0-201-99999-9 10 24.95
- **(b)** 10 24.95 0-210-99999-9

Exercise 14.11: What, if anything, is wrong with the following Sales data input operator? What would happen if we gave this operator the data in the previous exercise?

Click here to view code image

```
istream& operator>>(istream& in, Sales_data& s)
    double price;
    in >> s.bookNo >> s.units_sold >> price;
    s.revenue = s.units sold * price;
    return in;
```

Exercise 14.12: Define an input operator for the class you used in exercise 7.40 from § 7.5.1 (p. 291). Be sure the operator handles input errors.

14.3. Arithmetic and Relational Operators

Ordinarily, we define the arithmetic and relational operators as nonmember functions in order to allow conversions for either the left- or right-hand operand (§ 14.1, p. 555). These operators shouldn't need to change the state of either operand, so the parameters are ordinarily references to const.

An arithmetic operator usually generates a new value that is the result of a computation on its two operands. That value is distinct from either operand and is calculated in a local variable. The operation returns a copy of this local as its result. Classes that define an arithmetic operator generally define the corresponding compound assignment operator as well. When a class has both operators, it is usually more efficient to define the arithmetic operator to use compound assignment:

Click here to view code image

```
// assumes that both objects refer to the same book
Sales_data
operator+(const Sales_data &lhs, const Sales_data &rhs)
{
    Sales_data sum = lhs; // copy data members from lhs into sum
    sum += rhs; // add rhs into sum
    return sum;
}
```

This definition is essentially identical to our original add function (§ 7.1.3, p. 261). We copy lhs into the local variable sum. We then use the Sales_data compound-assignment operator (which we'll define on page 564) to add the values from rhs into sum. We end the function by returning a copy of sum.

Classes that define both an arithmetic operator and the related compound assignment ordinarily ought to implement the arithmetic operator by using the compound assignment.

Exercises Section 14.3

Exercise 14.13: Which other arithmetic operators (Table 4.1 (p. 139)), if any, do you think Sales_data ought to support? Define any you think the class should include.

Exercise 14.14: Why do you think it is more efficient to define operator+

to call operator+= rather than the other way around?

Exercise 14.15: Should the class you chose for exercise 7.40 from § 7.5.1 (p. 291) define any of the arithmetic operators? If so, implement them. If not, explain why not.

14.3.1. Equality Operators

Ordinarily, classes in C++ define the equality operator to test whether two objects are equivalent. That is, they usually compare every data member and treat two objects as equal if and only if all the corresponding members are equal. In line with this design philosophy, our Sales_data equality operator should compare the bookNo as well as the sales figures:

Click here to view code image

The definition of these functions is trivial. More important are the design principles that these functions embody:

- If a class has an operation to determine whether two objects are equal, it should define that function as operator== rather than as a named function:

 Users will expect to be able to compare objects using ==; providing == means they won't need to learn and remember a new name for the operation; and it is easier to use the library containers and algorithms with classes that define the == operator.
- If a class defines operator==, that operator ordinarily should determine whether the given objects contain equivalent data.
- Ordinarily, the equality operator should be transitive, meaning that if a == b and b == c are both true, then a == c should also be true.
- If a class defines operator==, it should also define operator!=. Users will expect that if they can use == then they can also use !=, and vice versa.
- One of the equality or inequality operators should delegate the work to the other. That is, one of these operators should do the real work to compare objects. The other should call the one that does the real work.

Best Practices

Classes for which there is a logical meaning for equality normally should define operator == . Classes that define == make it easier for users to use the class with the library algorithms.

Exercises Section 14.3.1

Exercise 14.16: Define equality and inequality operators for your StrBlob (§ 12.1.1, p. 456), StrBlobPtr (§ 12.1.6, p. 474), StrVec (§ 13.5, p. 526), and String (§ 13.5, p. 531) classes.

Exercise 14.17: Should the class you chose for exercise 7.40 from § 7.5.1 (p. 291) define the equality operators? If so, implement them. If not, explain why not.

14.3.2. Relational Operators

Classes for which the equality operator is defined also often (but not always) have relational operators. In particular, because the associative containers and some of the algorithms use the less-than operator, it can be useful to define an operator<.

Ordinarily the relational operators should

- 1. Define an ordering relation that is consistent with the requirements for use as a key to an associative container (§ 11.2.2, p. 424); and
- 2. Define a relation that is consistent with == if the class has both operators. In particular, if two objects are !=, then one object should be < the other.

Although we might think our Sales_data class should support the relational operators, it turns out that it probably should not do so. The reasons are subtle and are worth understanding.

We might think that we'd define < similarly to compareIsbn (§ 11.2.2, p. 425). That function compared Sales_data objects by comparing their ISBNS. Although compareIsbn provides an ordering relation that meets requirment 1, that function yields results that are inconsistent with our definition of ==. As a result, it does not meet requirement 2.

The Sales_data == operator treats two transactions with the same ISBN as unequal if they have different revenue or units_sold members. If we defined the < operator to compare only the ISBN member, then two objects with the same ISBN but different units_sold or revenue would compare as unequal, but neither object would be less than the other. Ordinarily, if we have two objects, neither of which is less than the other, then we expect that those objects are equal.

We might think that we should, therefore, define operator< to compare each data element in turn. We could define operator to compare objects with equal isbns by looking next at the units_sold and then at the revenue members.

However, there is nothing essential about this ordering. Depending on how we plan to use the class, we might want to define the order based first on either revenue or units sold. We might want those objects with fewer units sold to be "less than" those with more. Or we might want to consider those with smaller revenue "less than" those with more.

For Sales_data, there is no single logical definition of <. Thus, it is better for this class not to define < at all.

Best Practices

If a single logical definition for < exists, classes usually should define the < operator. However, if the class also has ==, define < only if the definitions of < and == yield consistent results.

Exercises Section 14.3.2

Exercise 14.18: Define relational operators for your StrBlob, StrBlobPtr, StrVec, and String classes.

Exercise 14.19: Should the class you chose for exercise 7.40 from § 7.5.1 (p. 291) define the relational operators? If so, implement them. If not, explain why not.

14.4. Assignment Operators

In addition to the copy- and move-assignment operators that assign one object of the class type to another object of the same type (§ 13.1.2, p. 500, and § 13.6.2, p. 536), a class can define additional assignment operators that allow other types as the right-hand operand.

As one example, in addition to the copy- and move-assignment operators, the library vector class defines a third assignment operator that takes a braced list of elements (§ 9.2.5, p. 337). We can use this operator as follows:

```
vector<string> v;
v = {"a", "an", "the"};
```

We can add this operator to our StrVec class (§ 13.5, p. 526) as well:

Click here to view code image

```
class StrVec {
public:
    StrVec &operator=(std::initializer_list<std::string>);
    // other members as in § 13.5 (p. 526)
};
```

To be consistent with assignment for the built-in types (and with the copy- and move-assignment operators we already defined), our new assignment operator will return a reference to its left-hand operand:

Click here to view code image

```
StrVec &StrVec::operator=(initializer_list<string> il)
{
    // alloc_n_copy allocates space and copies elements from the given range
    auto data = alloc_n_copy(il.begin(), il.end());
    free();    // destroy the elements in this object and free the space
    elements = data.first; // update data members to point to the new
space
    first_free = cap = data.second;
    return *this;
}
```

As with the copy- and move-assignment operators, other overloaded assignment operators have to free the existing elements and create new ones. Unlike the copy- and move-assignment operators, this operator does not need to check for self-assignment. The parameter is an initializer_list<string> (§ 6.2.6, p. 220), which means that il cannot be the same object as the one denoted by this.

Note

Assignment operators can be overloaded. Assignment operators, regardless of parameter type, must be defined as member functions.

Compound-Assignment Operators

Compound assignment operators are not required to be members. However, we prefer to define all assignments, including compound assignments, in the class. For consistency with the built-in compound assignment, these operators should return a reference to their left-hand operand. For example, here is the definition of the

Sales_data compound-assignment operator:

Click here to view code image

```
// member binary operator: left-hand operand is bound to the implicit this pointer
// assumes that both objects refer to the same book
Sales_data& Sales_data::operator+=(const Sales_data &rhs)
    units_sold += rhs.units_sold;
    revenue += rhs.revenue;
    return *this;
```

Best Practices

Assignment operators must, and ordinarily compound-assignment operators should, be defined as members. These operators should return a reference to the left-hand operand.

14.5. Subscript Operator

Classes that represent containers from which elements can be retrieved by position often define the subscript operator, operator[].

Exercises Section 14.4

Exercise 14.20: Define the addition and compound-assignment operators for your Sales_data class.

Exercise 14.21: Write the Sales_data operators so that + does the actual addition and += calls +. Discuss the disadvantages of this approach compared to the way these operators were defined in § 14.3 (p. 560) and § 14.4 (p. 564).

Exercise 14.22: Define a version of the assignment operator that can assign a string representing an ISBN to a Sales_data.

Exercise 14.23: Define an initializer list assignment operator for your version of the StrVec class.

Exercise 14.24: Decide whether the class you used in exercise 7.40 from § 7.5.1 (p. 291) needs a copy- and move-assignment operator. If so, define those operators.

Exercise 14.25: Implement any other assignment operators your class should define. Explain which types should be used as operands and why.

The subscript operator must be a member function.

To be compatible with the ordinary meaning of subscript, the subscript operator usually returns a reference to the element that is fetched. By returning a reference, subscript can be used on either side of an assignment. Consequently, it is also usually a good idea to define both const and nonconst versions of this operator. When applied to a const object, subscript should return a reference to const so that it is not possible to assign to the returned object.

Best Practices

If a class has a subscript operator, it usually should define two versions: one that returns a plain reference and the other that is a const member and returns a reference to const.

As an example, we'll define subscript for StrVec (§ 13.5, p. 526):

Click here to view code image

```
class StrVec {
public:
    std::string& operator[](std::size_t n)
         { return elements[n]; }
    const std::string& operator[](std::size_t n) const
          {    return elements[n];    }
    // other members as in § 13.5 (p. 526)
private:
    std::string *elements; // pointer to the first element in the array
};
```

We can use these operators similarly to how we subscript a vector or array. Because subscript returns a reference to an element, if the StrVec is nonconst, we can assign to that element; if we subscript a const object, we can't:

```
// assume svec is a StrVec
const StrVec cvec = svec; // copy elements from svec into cvec
// if svec has any elements, run the string empty function on the first one
if (svec.size() && svec[0].empty())
     svec[0] = "zero"; // ok: subscript returns a reference to a string
     cvec[0] = "Zip"; // error: subscripting cvec returns a reference to
const
```

Exercises Section 14.5

Exercise 14.26: Define subscript operators for your StrVec, String, StrBlob, and StrBlobPtr classes.

14.6. Increment and Decrement Operators

The increment (++) and decrement (--) operators are most often implemented for iterator classes. These operators let the class move between the elements of a sequence. There is no language requirement that these operators be members of the class. However, because these operators change the state of the object on which they operate, our preference is to make them members.

For the built-in types, there are both prefix and postfix versions of the increment and decrement operators. Not surprisingly, we can define both the prefix and postfix instances of these operators for our own classes as well. We'll look at the prefix versions first and then implement the postfix ones.

Best Practices

Classes that define increment or decrement operators should define both the prefix and postfix versions. These operators usually should be defined as members.

Defining Prefix Increment/Decrement Operators

To illustrate the increment and decrement operators, we'll define these operators for our StrBlobPtr class (§ 12.1.6, p. 474):

Click here to view code image

```
class StrBlobPtr {
public:
     // increment and decrement
    StrBlobPtr& operator++();
                                          // prefix operators
    StrBlobPtr& operator--();
     // other members as before
};
```

Best Practices

To be consistent with the built-in operators, the prefix operators should

return a reference to the incremented or decremented object.

The increment and decrement operators work similarly to each other—they call check to verify that the StrBlobPtr is still valid. If so, check also verifies that its given index is valid. If check doesn't throw an exception, these operators return a reference to this object.

In the case of increment, we pass the current value of curr to check. So long as that value is less than the size of the underlying vector, check will return. If curr is already at the end of the vector, check will throw:

Click here to view code image

The decrement operator decrements curr before calling check. That way, if curr (which is an unsigned number) is already zero, the value that we pass to check will be a large positive value representing an invalid subscript (§ 2.1.2, p. 36).

Differentiating Prefix and Postfix Operators

There is one problem with defining both the prefix and postfix operators: Normal overloading cannot distinguish between these operators. The prefix and postfix versions use the same symbol, meaning that the overloaded versions of these operators have the same name. They also have the same number and type of operands.

To solve this problem, the postfix versions take an extra (unused) parameter of type int. When we use a postfix operator, the compiler supplies 0 as the argument for this parameter. Although the postfix function can use this extra parameter, it usually should not. That parameter is not needed for the work normally performed by a postfix operator. Its sole purpose is to distinguish a postfix function from the prefix version.

We can now add the postfix operators to StrBlobPtr:

Click here to view code image

```
class StrBlobPtr {
public:
    // increment and decrement
    StrBlobPtr operator++(int); // postfix operators
    StrBlobPtr operator--(int);
    // other members as before
};
```

* Best Practices

To be consistent with the built-in operators, the postfix operators should return the old (unincremented or undecremented) value. That value is returned as a value, not a reference.

The postfix versions have to remember the current state of the object before incrementing the object:

Click here to view code image

```
// postfix: increment/decrement the object but return the unchanged value
StrBlobPtr StrBlobPtr::operator++(int)
     // no check needed here; the call to prefix increment will do the check
     StrBlobPtr ret = *this;
                                    // save the current value
     ++*this;
                // advance one element; prefix ++ checks the increment
     return ret; // return the saved state
StrBlobPtr StrBlobPtr::operator--(int)
     // no check needed here; the call to prefix decrement will do the check
     StrBlobPtr ret = *this;
                                   // save the current value
      --*this; // move backward one element; prefix -- checks the
decrement
     return ret; // return the saved state
```

Each of our operators calls its own prefix version to do the actual work. For example, the postfix increment operator executes

```
++*this
```

This expression calls the prefix increment operator. That operator checks that the increment is safe and either throws an exception or increments curr. Assuming

check doesn't throw an exception, the postfix functions return the stored copy in ret. Thus, after the return, the object itself has been advanced, but the value returned reflects the original, unincremented value.

Note

The int parameter is not used, so we do not give it a name.

Calling the Postfix Operators Explicitly

As we saw on page 553, we can explicitly call an overloaded operator as an alternative to using it as an operator in an expression. If we want to call the postfix version using a function call, then we must pass a value for the integer argument:

Click here to view code image

```
StrBlobPtr p(a1); // p points to the vector inside al
p.operator++(0); // call postfix operator++
p.operator++(); // call prefix operator++
```

The value passed usually is ignored but is necessary in order to tell the compiler to use the postfix version.

Exercises Section 14.6

Exercise 14.27: Add increment and decrement operators to your StrBlobPtr class.

Exercise 14.28: Define addition and subtraction for StrBlobPtr so that these operators implement pointer arithmetic (§ 3.5.3, p. 119).

Exercise 14.29: We did not define a const version of the increment and decrement operators. Why not?

14.7. Member Access Operators

The dereference (*) and arrow (->) operators are often used in classes that represent iterators and in smart pointer classes (§ 12.1, p. 450). We can logically add these operators to our StrBlobPtr class as well:

```
class StrBlobPtr {
public:
```

```
std::string& operator*() const
     { auto p = check(curr, "dereference past end");
       return (*p)[curr]; // (*p) is the vector to which this object points
    std::string* operator->() const
    { // delegate the real work to the dereference operator
     return & this->operator*();
    // other members as before
};
```

The dereference operator checks that curr is still in range and, if so, returns a reference to the element denoted by curr. The arrow operator avoids doing any work of its own by calling the dereference operator and returning the address of the element returned by that operator.

Operator arrow must be a member. The dereference operator is not required to be a member but usually should be a member as well.

It is worth noting that we've defined these operators as const members. Unlike the increment and decrment operators, fetching an element doesn't change the state of a StrBlobPtr. Also note that these operators return a reference or pointer to nonconst string. They do so because we know that a StrBlobPtr can only be bound to a nonconst StrBlob (§ 12.1.6, p. 474).

We can use these operators the same way that we've used the corresponding operations on pointers or vector iterators:

Click here to view code image

```
StrBlob a1 = {"hi", "bye", "now"};
StrBlobPtr p(a1);
                                // p points to the vector inside al
*p = "okay";
                                // assigns to the first element in al
cout << p->size() << endl; // prints 4, the size of the first element in</pre>
a1
cout << (*p).size() << endl; // equivalent to p->size()
```

Constraints on the Return from Operator Arrow

As with most of the other operators (although it would be a bad idea to do so), we can define operator* to do whatever processing we like. That is, we can define operator* to return a fixed value, say, 42, or print the contents of the object to which it is applied, or whatever. The same is not true for overloaded arrow. The arrow operator never loses its fundamental meaning of member access. When we overload

arrow, we change the object from which arrow fetches the specified member. We cannot change the fact that arrow fetches a member.

When we write point->mem, point must be a pointer to a class object or it must be an object of a class with an overloaded operator->. Depending on the type of point, writing point->mem is equivalent to

Click here to view code image

```
(*point).mem;
                             // point is a built-in pointer type
point.operator()->mem; // point is an object of class type
```

Otherwise the code is in error. That is, point->mem executes as follows:

- **1.** If point is a pointer, then the built-in arrow operator is applied, which means this expression is a synonym for (*point).mem. The pointer is dereferenced and the indicated member is fetched from the resulting object. If the type pointed to by point does not have a member named mem, then the code is in error.
- 2. If point is an object of a class that defines operator->, then the result of point.operator->() is used to fetch mem. If that result is a pointer, then step 1 is executed on that pointer. If the result is an object that itself has an overloaded operator->(), then this step is repeated on that object. This process continues until either a pointer to an object with the indicated member is returned or some other value is returned, in which case the code is in error.

The overloaded arrow operator must return either a pointer to a class type or an object of a class type that defines its own operator arrow.

Exercises Section 14.7

Exercise 14.30: Add dereference and arrow operators to your StrBlobPtr class and to the ConstStrBlobPtr class that you defined in exercise 12.22 from § 12.1.6 (p. 476). Note that the operators in constStrBlobPtr must return const references because the data member in constStrBlobPtr points to a const vector.

Exercise 14.31: Our StrBlobPtr class does not define the copy constructor, assignment operator, or a destructor. Why is that okay?

Exercise 14.32: Define a class that holds a pointer to a StrBlobPtr. Define the overloaded arrow operator for that class.

14.8. Function-Call Operator

Classes that overload the call operator allow objects of its type to be used as if they were a function. Because such classes can also store state, they can be more flexible than ordinary functions.

As a simple example, the following struct, named absInt, has a call operator that returns the absolute value of its argument:

Click here to view code image

```
struct absInt {
    int operator()(int val) const {
        return val < 0 ? -val : val;
    }
};</pre>
```

This class defines a single operation: the function-call operator. That operator takes an argument of type int and returns the argument's absolute value.

We use the call operator by applying an argument list to an absInt object in a way that looks like a function call:

Click here to view code image

```
int i = -42;
absInt absObj;  // object that has a function-call operator
int ui = absObj(i); // passes i to absObj.operator()
```

Even though absobj is an object, not a function, we can "call" this object. Calling an object runs its overloaded call operator. In this case, that operator takes an int value and returns its absolute value.

Note

The function-call operator must be a member function. A class may define multiple versions of the call operator, each of which must differ as to the number or types of their parameters.

Objects of classes that define the call operator are referred to as **function objects**. Such objects "act like functions" because we can call them.

Function-Object Classes with State

Like any other class, a function-object class can have additional members aside from

operator(). Function-object classes often contain data members that are used to customize the operations in the call operator.

As an example, we'll define a class that prints a string argument. By default, our class will write to cout and will print a space following each string. We'll also let users of our class provide a different stream on which to write and provide a different separator. We can define this class as follows:

Click here to view code image

```
class PrintString {
public:
    PrintString(ostream &o = cout, char c = ' '):
        os(o), sep(c) { }
    void operator()(const string &s) const { os << s << sep; }
private:
    ostream &os; // stream on which to write
    char sep; // character to print after each output
};</pre>
```

Our class has a constructor that takes a reference to an output stream and a character to use as the separator. It uses cout and a space as default arguments (§ 6.5.1, p. 236) for these parameters. The body of the function-call operator uses these members when it prints the given string.

When we define PrintString objects, we can use the defaults or supply our own values for the separator or output stream:

Click here to view code image

```
PrintString printer; // uses the defaults; prints to cout
printer(s); // prints s followed by a space on cout
PrintString errors(cerr, '\n');
errors(s); // prints s followed by a newline on cerr
```

Function objects are most often used as arguments to the generic algorithms. For example, we can use the library for_each algorithm (§ 10.3.2, p. 391) and our PrintString class to print the contents of a container:

Click here to view code image

```
for_each(vs.begin(), vs.end(), PrintString(cerr, '\n'));
```

The third argument to for_each is a temporary object of type PrintString that we initialize from cerr and a newline character. The call to for_each will print each element in vs to cerr followed by a newline.

Exercises Section 14.8

Exercise 14.33: How many operands may an overloaded function-call operator take?

Exercise 14.34: Define a function-object class to perform an if-then-else operation: The call operator for this class should take three parameters. It should test its first parameter and if that test succeeds, it should return its second parameter; otherwise, it should return its third parameter.

Exercise 14.35: Write a class like PrintString that reads a line of input from an istream and returns a string representing what was read. If the read fails, return the empty string.

Exercise 14.36: Use the class from the previous exercise to read the standard input, storing each line as an element in a vector.

Exercise 14.37: Write a class that tests whether two values are equal. Use that object and the library algorithms to write a program to replace all instances of a given value in a sequence.

14.8.1. Lambdas Are Function Objects

In the previous section, we used a PrintString object as an argument in a call to for_each. This usage is similar to the programs we wrote in § 10.3.2 (p. 388) that used lambda expressions. When we write a lambda, the compiler translates that expression into an unnamed object of an unnamed class (§ 10.3.3, p. 392). The classes generated from a lambda contain an overloaded function-call operator. For example, the lambda that we passed as the last argument to stable_sort:

Click here to view code image

acts like an unnamed object of a class that would look something like

Click here to view code image

```
class ShorterString {
public:
          bool operator()(const string &s1, const string &s2)
const
          { return s1.size() < s2.size(); }
};</pre>
```

The generated class has a single member, which is a function-call operator that takes two strings and compares their lengths. The parameter list and function body are the same as the lambda. As we saw in § 10.3.3 (p. 395), by default, lambdas may not change their captured variables. As a result, by default, the function-call operator in a class generated from a lambda is a const member function. If the lambda is declared as mutable, then the call operator is not const.

We can rewrite the call to stable_sort to use this class instead of the lambda expression:

Click here to view code image

```
stable_sort(words.begin(), words.end(), ShorterString());
```

The third argument is a newly constructed ShorterString object. The code in stable_sort will "call" this object each time it compares two strings. When the object is called, it will execute the body of its call operator, returning true if the first string's size is less than the second's.

Classes Representing Lambdas with Captures

As we've seen, when a lambda captures a variable by reference, it is up to the program to ensure that the variable to which the reference refers exists when the lambda is executed (§ 10.3.3, p. 393). Therefore, the compiler is permitted to use the reference directly without storing that reference as a data member in the generated class.

In contrast, variables that are captured by value are copied into the lambda (§ 10.3.3, p. 392). As a result, classes generated from lambdas that capture variables by value have data members corresponding to each such variable. These classes also have a constructor to initialize these data members from the value of the captured variables. As an example, in § 10.3.2 (p. 390), the lambda that we used to find the first string whose length was greater than or equal to a given bound:

Click here to view code image

would generate a class that looks something like

Click here to view code image

Unlike our ShorterString class, this class has a data member and a constructor to initialize that member. This synthesized class does not have a default constructor; to use this class, we must pass an argument:

Click here to view code image

```
// get an iterator to the first element whose size() is >= sz
auto wc = find_if(words.begin(), words.end(), SizeComp(sz));
```

Classes generated from a lambda expression have a deleted default constructor, deleted assignment operators, and a default destructor. Whether the class has a defaulted or deleted copy/move constructor depends in the usual ways on the types of the captured data members (§ 13.1.6, p. 508, and § 13.6.2, p. 537).

Exercises Section 14.8.1

Exercise 14.38: Write a class that tests whether the length of a given string matches a given bound. Use that object to write a program to report how many words in an input file are of sizes 1 through 10 inclusive.

Exercise 14.39: Revise the previous program to report the count of words that are sizes 1 through 9 and 10 or more.

Exercise 14.40: Rewrite the biggies function from § 10.3.2 (p. 391) to use function-object classes in place of lambdas.

Exercise 14.41: Why do you suppose the new standard added lambdas? Explain when you would use a lambda and when you would write a class instead.

14.8.2. Library-Defined Function Objects

The standard library defines a set of classes that represent the arithmetic, relational, and logical operators. Each class defines a call operator that applies the named operation. For example, the plus class has a function-call operator that applies + to a pair of operands; the modulus class defines a call operator that applies the binary % operator; the equal_to class applies ==; and so on.

These classes are templates to which we supply a single type. That type specifies the parameter type for the call operator. For example, plus<string> applies the string addition operator to string objects; for plus<int> the operands are ints; plus<Sales_data> applies + to Sales_datas; and so on:

```
// to intAdd::operator(int, int)
sum = intAdd(10, intNegate(10));  // sum = 0
```

These types, listed in Table 14.2, are defined in the functional header.

Table 14.2. Library Function Objects

```
Arithmetic
                  Relational
                                       Logical
plus<Type>
                 equal to<Type>
                                       logical and<Type>
                                       logical or<Type>
minus<Type>
                 not equal to<Type>
multiplies<Type> greater<Type>
                                       logical not<Type>
divides<Type>
                 greater_equal<Type>
modulus<Type>
                 less<Type>
negate<Type>
                 less equal<Type>
```

Using a Library Function Object with the Algorithms

The function-object classes that represent operators are often used to override the default operator used by an algorithm. As we've seen, by default, the sorting algorithms use operator<, which ordinarily sorts the sequence into ascending order. To sort into descending order, we can pass an object of type greater. That class generates a call operator that invokes the greater-than operator of the underlying element type. For example, if svec is a vector<string>,

Click here to view code image

```
// passes a temporary function object that applies the < operator to two strings
sort(svec.begin(), svec.end(), greater<string>());
```

sorts the vector in descending order. The third argument is an unnamed object of type greater<string>. When sort compares elements, rather than applying the < operator for the element type, it will call the given greater function object. That object applies > to the string elements.

One important aspect of these library function objects is that the library guarantees that they will work for pointers. Recall that comparing two unrelated pointers is undefined (§ 3.5.3, p. 120). However, we might want to sort a vector of pointers based on their addresses in memory. Although it would be undefined for us to do so directly, we can do so through one of the library function objects:

```
vector<string *> nameTable; // vector of pointers
// error: the pointers in nameTable are unrelated, so < is undefined
sort(nameTable.begin(), nameTable.end(),
      [](string *a, string *b) { return a < b; });
// ok: library guarantees that less on pointer types is well defined
sort(nameTable.begin(), nameTable.end(), less<string*>());
```

It is also worth noting that the associative containers use less<key_type> to order their elements. As a result, we can define a set of pointers or use a pointer as the key in a map without specifying less directly.

Exercises Section 14.8.2

Exercise 14.42: Using library function objects and adaptors, define an expression to

- (a) Count the number of values that are greater than 1024
- (b) Find the first string that is not equal to pooh
- (c) Multiply all values by 2

Exercise 14.43: Using library function objects, determine whether a given int value is divisible by any element in a container of ints.

14.8.3. Callable Objects and function

C++ has several kinds of callable objects: functions and pointers to functions, lambdas (§ 10.3.2, p. 388), objects created by bind (§ 10.3.4, p. 397), and classes that overload the function-call operator.

Like any other object, a callable object has a type. For example, each lambda has its own unique (unnamed) class type. Function and function-pointer types vary by their return type and argument types, and so on.

However, two callable objects with different types may share the same **call signature**. The call signature specifies the type returned by a call to the object and the argument type(s) that must be passed in the call. A call signature corresponds to a function type. For example:

```
int(int, int)
```

is a function type that takes two ints and returns an int.

Different Types Can Have the Same Call Signature

Sometimes we want to treat several callable objects that share a call signature as if they had the same type. For example, consider the following different types of callable objects:

```
// ordinary function
int add(int i, int j) { return i + j; }
// lambda, which generates an unnamed function-object class
```

```
auto mod = [](int i, int j) { return i % j; };
// function-object class
struct div {
   int operator()(int denominator, int divisor) {
      return denominator / divisor;
   }
};
```

Each of these callables applies an arithmetic operation to its parameters. Even though each has a distinct type, they all share the same call signature:

```
int(int, int)
```

We might want to use these callables to build a simple desk calculator. To do so, we'd want to define a **function table** to store "pointers" to these callables. When the program needs to execute a particular operation, it will look in the table to find which function to call.

In C++, function tables are easy to implement using a map. In this case, we'll use a string corresponding to an operator symbol as the key; the value will be the function that implements that operator. When we want to evaluate a given operator, we'll index the map with that operator and call the resulting element.

If all our functions were freestanding functions, and assuming we were handling only binary operators for type int, we could define the map as

Click here to view code image

```
// maps an operator to a pointer to a function taking two ints and returning an int
map<string, int(*)(int,int)> binops;
```

We could put a pointer to add into binops as follows:

Click here to view code image

```
// ok: add is a pointer to function of the appropriate type
binops.insert({"+", add}); // {"+", add} is a pair § 11.2.3 (p. 426)
```

However, we can't store mod or div in binops:

Click here to view code image

```
binops.insert({"%", mod}); // error: mod is not a pointer to function
```

The problem is that mod is a lambda, and each lambda has its own class type. That type does not match the type of the values stored in binops.

The Library function Type

We can solve this problem using a new library type named **function** that is defined in the functional header; Table 14.3 (p. 579) lists the operations defined by function.

Table 14.3. Operations on function

```
f is a null function object that can store callable objects
function<T> f;
                               with a call signature that is equivalent to the function type T
                               (i.e., T is retType (args)).
function<T> f (nullptr); Explicitly construct a null function.
                               Stores a copy of the callable object obj in f.
function<T> f(obj);
                               Use f as a condition; true if f holds a callable object;
£
                               false otherwise.
                               Calls the object in f passing args.
f (args)
Types defined as members of function<T>
                               The type returned by this function type's callable object.
result type
                               Types defined when T has exactly one or two arguments.
argument type
first argument type
                               If T has one argument, argument type is a synonym for
second argument type
                               that type. If T has two arguments, first argument type
                               and second argument type are synonyms for those ar-
                               gument types.
```

function is a template. As with other templates we've used, we must specify additional information when we create a function type. In this case, that information is the call signature of the objects that this particular function type can represent. As with other templates, we specify the type inside angle brackets:

```
function<int(int, int)>
```

Here we've declared a function type that can represent callable objects that return an int result and have two int parameters. We can use that type to represent any of our desk calculator types:

Click here to view code image

We can now redefine our map using this function type:

```
// table of callable objects corresponding to each binary operator
// all the callables must take two ints and return an int
```

```
// an element can be a function pointer, function object, or lambda
map<string, function<int(int, int)>> binops;
```

We can add each of our callable objects, be they function pointers, lambdas, or function objects, to this map:

Click here to view code image

Our map has five elements. Although the underlying callable objects all have different types from one another, we can store each of these distinct types in the common function<int(int, int) > type.

As usual, when we index a map, we get a reference to the associated value. When we index binops, we get a reference to an object of type function. The function type overloads the call operator. That call operator takes its own arguments and passes them along to its stored callable object:

Click here to view code image

```
binops["+"](10, 5); // calls add(10, 5)
binops["-"](10, 5); // uses the call operator of the minus<int> object
binops["/"](10, 5); // uses the call operator of the div object
binops["*"](10, 5); // calls the lambda function object
binops["%"](10, 5); // calls the lambda function object
```

Here we call each of the operations stored in binops. In the first call, the element we get back holds a function pointer that points to our add function. Calling binops["+"](10, 5) uses that pointer to call add, passing it the values 10 and 5. In the next call, binops["-"], returns a function that stores an object of type std::minus<int>. We call that object's call operator, and so on.

Overloaded Functions and function

We cannot (directly) store the name of an overloaded function in an object of type function:

```
int add(int i, int j) { return i + j; }
Sales_data add(const Sales_data&, const Sales_data&);
map<string, function<int(int, int)>> binops;
```

```
binops.insert( {"+", add} ); // error: which add?
```

One way to resolve the ambiguity is to store a function pointer (§ 6.7, p. 247) instead of the name of the function:

Click here to view code image

```
int (*fp)(int,int) = add; // pointer to the version of add that takes two
ints
```

binops.insert({"+", fp}); // ok: fp points to the right version of add

Alternatively, we can use a lambda to disambiguate:

Click here to view code image

```
// ok: use a lambda to disambiguate which version of add we want to use
binops.insert( {"+", [](int a, int b) {return add(a, b);} }
);
```

The call inside the lambda body passes two ints. That call can match only the version of add that takes two ints, and so that is the function that is called when the lambda is executed.

The function class in the new library is not related to classes named unary_function and binary_function that were part of earlier versions of the library. These classes have been deprecated by the more general bind function (§ 10.3.4, p. 401).

Exercises Section 14.8.3

Exercise 14.44: Write your own version of a simple desk calculator that can handle binary operations.

14.9. Overloading, Conversions, and Operators

In § 7.5.4 (p. 294) we saw that a nonexplicit constructor that can be called with one argument defines an implicit conversion. Such constructors convert an object from the argument's type to the class type. We can also define conversions from the class type. We define a conversion from a class type by defining a conversion operator. Converting constructors and conversion operators define class-type conversions. Such conversions are also referred to as user-defined conversions.

14.9.1. Conversion Operators

A conversion operator is a special kind of member function that converts a value of a class type to a value of some other type. A conversion function typically has the general form

```
operator type() const;
```

where type represents a type. Conversion operators can be defined for any type (other than void) that can be a function return type (§ 6.1, p. 204). Conversions to an array or a function type are not permitted. Conversions to pointer types—both data and function pointers—and to reference types are allowed.

Conversion operators have no explicitly stated return type and no parameters, and they must be defined as member functions. Conversion operations ordinarily should not change the object they are converting. As a result, conversion operators usually should be defined as const members.

A conversion function must be a member function, may not specify a return type, and must have an empty parameter list. The function usually should be const.

Defining a Class with a Conversion Operator

As an example, we'll define a small class that represents an integer in the range of 0 to 255:

Click here to view code image

```
class SmallInt {
public:
    SmallInt(int i = 0): val(i)
        if (i < 0 | i > 255)
            throw std::out_of_range("Bad SmallInt value");
    operator int() const { return val; }
private:
    std::size t val;
};
```

Our Smallint class defines conversions to and from its type. The constructor converts values of arithmetic type to a Smallint. The conversion operator converts SmallInt objects to int:

Click here to view code image

```
SmallInt si;
si = 4; // implicitly converts 4 to SmallInt then calls SmallInt::operator=
si + 3; // implicitly converts si to int followed by integer addition
```

Although the compiler will apply only one user-defined conversion at a time (§ 4.11.2, p. 162), an implicit user-defined conversion can be preceded or followed by a standard (built-in) conversion (§ 4.11.1, p. 159). As a result, we can pass any arithmetic type to the SmallInt constructor. Similarly, we can use the converion operator to convert a SmallInt to an int and then convert the resulting int value to another arithmetic type:

Click here to view code image

```
// the double argument is converted to int using the built-in conversion
SmallInt si = 3.14; // calls the SmallInt(int) constructor
// the SmallInt conversion operator converts si to int;
si + 3.14; // that int is converted to double using the built-in conversion
```

Because conversion operators are implicitly applied, there is no way to pass arguments to these functions. Hence, conversion operators may not be defined to take parameters. Although a conversion function does not specify a return type, each conversion function must return a value of its corresponding type:

Click here to view code image

Caution: Avoid Overuse of Conversion Functions

As with using overloaded operators, judicious use of conversion operators can greatly simplify the job of a class designer and make using a class easier. However, some conversions can be misleading. Conversion operators are misleading when there is no obvious single mapping between the class type and the conversion type.

For example, consider a class that represents a Date. We might think it would be a good idea to provide a conversion from Date to int. However, what value should the conversion function return? The function might return a decimal representation of the year, month, and day. For example, July 30,

1989 might be represented as the int value 19800730. Alternatively, the conversion operator might return an int representing the number of days that have elapsed since some epoch point, such as January 1, 1970. Both these conversions have the desirable property that later dates correspond to larger integers, and so either might be useful.

The problem is that there is no single one-to-one mapping between an object of type Date and a value of type int. In such cases, it is better not to define the conversion operator. Instead, the class ought to define one or more ordinary members to extract the information in these various forms.

Conversion Operators Can Yield Suprising Results

In practice, classes rarely provide conversion operators. Too often users are more likely to be surprised if a conversion happens automatically than to be helped by the existence of the conversion. However, there is one important exception to this rule of thumb: It is not uncommon for classes to define conversions to bool.

Under earlier versions of the standard, classes that wanted to define a conversion to bool faced a problem: Because bool is an arithmetic type, a class-type object that is converted to bool can be used in any context where an arithmetic type is expected. Such conversions can happen in surprising ways. In particular, if istream had a conversion to bool, the following code would compile:

Click here to view code image

```
int i = 42;
cin << i; // this code would be legal if the conversion to bool were not explicit!</pre>
```

This program attempts to use the output operator on an input stream. There is no << defined for istream, so the code is almost surely in error. However, this code could use the bool conversion operator to convert cin to bool. The resulting bool value would then be promoted to int and used as the left-hand operand to the built-in version of the left-shift operator. The promoted bool value (either 1 or 0) would be shifted left 42 positions.

explicit Conversion Operators

To prevent such problems, the new standard introduced **explicit conversion operators**:

```
class SmallInt {
public:
```

```
// the compiler won't automatically apply this conversion
explicit operator int() const { return val; }
// other members as before
};
```

As with an explicit constructor (§ 7.5.4, p. 296), the compiler won't (generally) use an explicit conversion operator for implicit conversions:

Click here to view code image

```
SmallInt si = 3; // ok: the SmallInt constructor is not explicit
si + 3; // error: implicit is conversion required, but operator int is explicit
static_cast<int>(si) + 3; // ok: explicitly request the conversion
```

If the conversion operator is explicit, we can still do the conversion. However, with one exception, we must do so explicitly through a cast.

The exception is that the compiler will apply an explicit conversion to an expression used as a condition. That is, an explicit conversion will be used implicitly to convert an expression used as

- The condition of an if, while, or do statement
- The condition expression in a for statement header
- An operand to the logical NOT (!), OR (||), or AND (&&) operators
- The condition expression in a conditional (?:) operator

Conversion to bool

In earlier versions of the library, the IO types defined a conversion to void*. They did so to avoid the kinds of problems illustrated above. Under the new standard, the IO library instead defines an explicit conversion to bool.

Whenever we use a stream object in a condition, we use the operator bool that is defined for the IO types. For example,

```
while (std::cin >> value)
```

The condition in the while executes the input operator, which reads into value and returns cin. To evaluate the condition, cin is implicitly converted by the istream operator bool conversion function. That function returns true if the condition state of cin is good (§ 8.1.2, p. 312), and false otherwise.

Conversion to bool is usually intended for use in conditions. As a result, operator bool ordinarily should be defined as explicit.

Exercises Section 14.9.1

Exercise 14.45: Write conversion operators to convert a Sales_data to string and to double. What values do you think these operators should return?

Exercise 14.46: Explain whether defining these Sales_data conversion operators is a good idea and whether they should be explicit.

Exercise 14.47: Explain the difference between these two conversion operators:

```
struct Integral {
    operator const int();
    operator int() const;
};
```

Exercise 14.48: Determine whether the class you used in exercise 7.40 from § 7.5.1 (p. 291) should have a conversion to bool. If so, explain why, and explain whether the operator should be explicit. If not, explain why not.

Exercise 14.49: Regardless of whether it is a good idea to do so, define a conversion to bool for the class from the previous exercise.

14.9.2. Avoiding Ambiguous Conversions

If a class has one or more conversions, it is important to ensure that there is only one way to convert from the class type to the target type. If there is more than one way to perform a conversion, it will be hard to write unambiguous code.

There are two ways that multiple conversion paths can occur. The first happens when two classes provide mutual conversions. For example, mutual conversions exist when a class A defines a converting constructor that takes an object of class B and B itself defines a conversion operator to type A.

The second way to generate multiple conversion paths is to define multiple conversions from or to types that are themselves related by conversions. The most obvious instance is the built-in arithmetic types. A given class ordinarily ought to define at most one conversion to or from an arithmetic type.

Ordinarily, it is a bad idea to define classes with mutual conversions or to define conversions to or from two arithmetic types.

In the following example, we've defined two ways to obtain an A from a B: either by using B's conversion operator or by using the A constructor that takes a B:

Click here to view code image

Because there are two ways to obtain an \mathtt{A} from a \mathtt{B} , the compiler doesn't know which conversion to run; the call to \mathtt{f} is ambiguous. This call can use the \mathtt{A} constructor that takes a \mathtt{B} , or it can use the \mathtt{B} conversion operator that converts a \mathtt{B} to an \mathtt{A} . Because these two functions are equally good, the call is in error.

If we want to make this call, we have to explicitly call the conversion operator or the constructor:

Click here to view code image

```
A al = f(b.operator A()); // ok: use B's conversion operator
A a2 = f(A(b)); // ok: use A's constructor
```

Note that we can't resolve the ambiguity by using a cast—the cast itself would have the same ambiguity.

Ambiguities and Multiple Conversions to Built-in Types

Ambiguities also occur when a class defines multiple conversions to (or from) types that are themselves related by conversions. The easiest case to illustrate—and one that is particularly problematic—is when a class defines constructors from or conversions to more than one arithmetic type.

For example, the following class has converting constructors from two different arithmetic types, and conversion operators to two different arithmetic types:

```
struct A {
    A(int = 0);  // usually a bad idea to have two
    A(double);  // conversions from arithmetic types
    operator int() const;  // usually a bad idea to have two
    operator double() const; // conversions to arithmetic types
    // other members

};
void f2(long double);
A a;
f2(a); // error ambiguous: f(A::operator int())
    // or f(A::operator double())
long lg;
A a2(lg); // error ambiguous: A::A(int) or A::A(double)
```

In the call to £2, neither conversion is an exact match to long double. However, either conversion can be used, followed by a standard conversion to get to long double. Hence, neither conversion is better than the other; the call is ambiguous.

We encounter the same problem when we try to initialize a2 from a long. Neither constructor is an exact match for long. Each would require that the argument be converted before using the constructor:

- Standard long to double conversion followed by A(double)
- Standard long to int conversion followed by A(int)

These conversion sequences are indistinguishable, so the call is ambiguous.

The call to £2, and the initialization of a2, are ambiguous because the standard conversions that were needed had the same rank (§ 6.6.1, p. 245). When a user-defined conversion is used, the rank of the standard conversion, if any, is used to select the best match:

Click here to view code image

```
short s = 42;
// promoting short to int is better than converting short to double
A a3(s); // uses A::A(int)
```

In this case, promoting a short to an int is preferred to converting the short to a double. Hence a3 is constructed using the A::A(int) constructor, which is run on the (promoted) value of s.

Note

When two user-defined conversions are used, the rank of the standard conversion, if any, *preceding* or *following* the conversion function is used to select the best match.

Overloaded Functions and Converting Constructors

Choosing among multiple conversions is further complicated when we call an overloaded function. If two or more conversions provide a viable match, then the conversions are considered equally good.

As one example, ambiguity problems can arise when overloaded functions take parameters that differ by class types that define the same converting constructors:

Caution: Conversions and Operators

Correctly designing the overloaded operators, conversion constructors, and conversion functions for a class requires some care. In particular, ambiguities are easy to generate if a class defines both conversion operators and overloaded operators. A few rules of thumb can be helpful:

- Don't define mutually converting classes—if class Foo has a constructor that takes an object of class Bar, do not give Bar a conversion operator to type Foo.
- Avoid conversions to the built-in arithmetic types. In particular, if you do define a conversion to an arithmetic type, then
- Do not define overloaded versions of the operators that take arithmetic types.
 If users need to use these operators, the conversion operation will convert objects of your type, and then the built-in operators can be used.
- Do not define a conversion to more than one arithmetic type. Let the standard conversions provide conversions to the other arithmetic types.

The easiest rule of all: With the exception of an explicit conversion to bool, avoid defining conversion functions and limit nonexplicit constructors to those that are "obviously right."

```
struct C {
        C(int);
        // other members
};
struct D {
        D(int);
        // other members
};
void manip(const C&);
void manip(const D&);
manip(10); // error ambiguous: manip(C(10)) or manip(D(10))
```

Here both C and D have constructors that take an int. Either constructor can be used to match a version of manip. Hence, the call is ambiguous: It could mean convert the int to C and call the first version of manip, or it could mean convert the int to D and call the second version.

The caller can disambiguate by explicitly constructing the correct type:

Click here to view code image

```
manip(C(10)); // ok: calls manip(const C&)
```

Warning

Needing to use a constructor or a cast to convert an argument in a call to an overloaded function frequently is a sign of bad design.

Overloaded Functions and User-Defined Conversion

In a call to an overloaded function, if two (or more) user-defined conversions provide a viable match, the conversions are considered equally good. The rank of any standard conversions that might or might not be required is not considered. Whether a built-in conversion is also needed is considered only if the overload set can be matched using the same conversion function.

For example, our call to manip would be ambiguous even if one of the classes defined a constructor that required a standard conversion for the argument:

Click here to view code image

```
struct E {
     E(double);
     // other members
};
void manip2(const C&);
void manip2(const E&);
// error ambiguous: two different user-defined conversions could be used
manip2(10); // manip2(C(10)) or manip2(E(double(10)))
```

In this case, C has a conversion from int and E has a conversion from double. For the call manip2(10), both manip2 functions are viable:

- manip2(const C&) is viable because C has a converting constructor that takes an int. That constructor is an exact match for the argument.
- manip2(const E&) is viable because E has a converting constructor that takes a double and we can use a standard conversion to convert the int argument in order to use that converting constructor.

Because calls to the overloaded functions require *different* user-defined conversions from one another, this call is ambiguous. In particular, even though one of the calls requires a standard conversion and the other is an exact match, the compiler will still flag this call as an error.

Note

In a call to an overloaded function, the rank of an additional standard conversion (if any) matters only if the viable functions require the same user-defined conversion. If different user-defined conversions are needed, then the call is ambiguous.

14.9.3. Function Matching and Overloaded Operators

Overloaded operators are overloaded functions. Normal function matching (§ 6.4, p. 233) is used to determine which operator—built-in or overloaded—to apply to a given expression. However, when an operator function is used in an expression, the set of candidate functions is broader than when we call a function using the call operator. If a has a class type, the expression a *sym* b might be

Click here to view code image

```
a.operatorsym (b); // a has operatorsym as a member function
operatorsym(a, b); // operatorsym is an ordinary function
```

Unlike ordinary function calls, we cannot use the form of the call to distinquish whether we're calling a nonmember or a member function.

Exercises Section 14.9.2

Exercise 14.50: Show the possible class-type conversion sequences for the initializations of ex1 and ex2. Explain whether the initializations are legal or not.

Click here to view code image

```
struct LongDouble {
    LongDouble(double = 0.0);
    operator double();
    operator float();
};
LongDouble ldObj;
int ex1 = ldObj;
float ex2 = ldObj;
```

Exercise 14.51: Show the conversion sequences (if any) needed to call each

version of calc and explain why the best viable function is selected.

Click here to view code image

```
void calc(int);
void calc(LongDouble);
double dval;
calc(dval); // which calc?
```

When we use an overloaded operator with an operand of class type, the candidate functions include ordinary nonmember versions of that operator, as well as the built-in versions of the operator. Moreover, if the left-hand operand has class type, the overloaded versions of the operator, if any, defined by that class are also included.

When we call a named function, member and nonmember functions with the same name do *not* overload one another. There is no overloading because the syntax we use to call a named function distinguishes between member and nonmember functions. When a call is through an object of a class type (or through a reference or pointer to such an object), then only the member functions of that class are considered. When we use an overloaded operator in an expression, there is nothing to indicate whether we're using a member or nonmember function. Therefore, both member and nonmember versions must be considered.

Note

The set of candidate functions for an operator used in an expression can contain both nonmember and member functions.

As an example, we'll define an addition operator for our Smallint class:

Click here to view code image

We can use this class to add two SmallInts, but we will run into ambiguity problems if we attempt to perform mixed-mode arithmetic:

```
SmallInt s1, s2;
```

```
SmallInt s3 = s1 + s2; // uses overloaded operator+
int i = s3 + 0; // error: ambiguous
```

The first addition uses the overloaded version of + that takes two Smallint values. The second addition is ambiguous, because we can convert 0 to a Smallint and use the SmallInt version of +, or convert s3 to int and use the built-in addition operator on ints.

Warning

Providing both conversion functions to an arithmetic type and overloaded operators for the same class type may lead to ambiguities between the overloaded operators and the built-in operators.

Exercises Section 14.9.3

Exercise 14.52: Which operator+, if any, is selected for each of the addition expressions? List the candidate functions, the viable functions, and the type conversions on the arguments for each viable function:

Click here to view code image

```
struct LongDouble {
    // member operator+ for illustration purposes; + is usually a nonmember
    LongDouble operator+(const SmallInt&);
    // other members as in § 14.9.2 (p. 587)
};
LongDouble operator+(LongDouble&, double);
SmallInt si;
LongDouble ld;
ld = si + ld;
ld = ld + si;
```

Exercise 14.53: Given the definition of SmallInt on page 588, determine whether the following addition expression is legal. If so, what addition operator is used? If not, how might you change the code to make it legal?

```
SmallInt s1;
double d = s1 + 3.14;
```

Chapter Summary

An overloaded operator must either be a member of a class or have at least one operand of class type. Overloaded operators have the same number of operands, associativity, and precedence as the corresponding operator when applied to the builtin types. When an operator is defined as a member, its implicit this pointer is bound to the first operand. The assignment, subscript, function-call, and arrow operators must be class members.

Objects of classes that overload the function-call operator, operator(), are known as "function objects." Such objects are often used in combination with the standard algorithms. Lambda expressions are succinct ways to define simple function-object classes.

A class can define conversions to or from its type that are used automatically. Nonexplicit constructors that can be called with a single argument define conversions from the parameter type to the class type; nonexplicit conversion operators define conversions from the class type to other types.

Defined Terms

call signature Represents the interface of a callable object. A call signature includes the return type and a comma-separated list of argument types enclosed in parentheses.

class-type conversion Conversions to or from class types are defined by constructors and conversion operators, respectively. Nonexplicit constructors that take a single argument define a conversion from the argument type to the class type. Conversion operators define conversions from the class type to the specified type.

conversion operator A member function that defines a conversions from the class type to another type. A conversion operator must be a member of the class from which it converts and is usually a const member. These operators have no return type and take no parameters. They return a value convertible to the type of the conversion operator. That is, operator int returns an int, operator string returns a string, and so on.

explicit conversion operator Conversion operator preceded by the explicit keyword. Such operators are used for implicit conversions only in conditions.

function object Object of a class that defines an overloaded call operator. Function objects can be used where functions are normally expected.

function table Container, often a map or a vector, that holds values that can be called.

function template Library template that can represent any callable type.

overloaded operator Function that redefines the meaning of one of the built-in operators. Overloaded operator functions have the name operator followed by the symbol being defined. Overloaded operators must have at least one operand of class type. Overloaded operators have the same precedence, associativity and

number of operands as their built-in counterparts.

user-defined conversion A synonym for class-type conversion.

Chapter Summary

Defined Terms

Object-oriented programming is based on three fundamental concepts: data abstraction, which we covered in Chapter 7, and inheritance and dynamic binding, which we'll cover in this chapter.

Inheritance and dynamic binding affect how we write our programs in two ways: They make it easier to define new classes that are similar, but not identical, to other classes, and they make it easier for us to write programs that can ignore the details of how those similar types differ.

Many applications include concepts that are related to but slightly different from one another. For example, our bookstore might offer different pricing strategies for different books. Some books might be sold only at a given price. Others might be sold subject to a discount. We might give a discount to purchasers who buy a specified number of copies of the book. Or we might give a discount for only the first few copies purchased but charge full price for any bought beyond a given limit, and so on. Object-oriented programming (OOP) is a good match to this kind of application.

15.1. OOP: An Overview

The key ideas in **object-oriented programming** are data abstraction, inheritance, and dynamic binding. Using data abstraction, we can define classes that separate interface from implementation (Chapter 7). Through inheritance, we can define classes that model the relationships among similar types. Through dynamic binding, we can use objects of these types while ignoring the details of how they differ.

Inheritance

Classes related by **inheritance** form a hierarchy. Typically there is a **base class** at the root of the hierarchy, from which the other classes inherit, directly or indirectly. These inheriting classes are known as **derived classes**. The base class defines those members that are common to the types in the hierarchy. Each derived class defines those members that are specific to the derived class itself.

To model our different kinds of pricing strategies, we'll define a class named Quote, which will be the base class of our hierarchy. A Quote object will represent undiscounted books. From Quote we will inherit a second class, named Bulk_quote, to represent books that can be sold with a quantity discount.

These classes will have the following two member functions:

- isbn(), which will return the ISBN. This operation does not depend on the specifics of the inherited class(es); it will be defined only in class Quote.
- net_price(size_t), which will return the price for purchasing a specified number of copies of a book. This operation is type specific; both Quote and Bulk_quote will define their own version of this function.

In C++, a base class distinguishes functions that are type dependent from those that it expects its derived classes to inherit without change. The base class defines as **virtual** those functions it expects its derived classes to define for themselves. Using this knowledge, we can start to write our Quote class:

Click here to view code image

```
class Quote {
public:
    std::string isbn() const;
    virtual double net_price(std::size_t n) const;
};
```

A derived class must specify the class(es) from which it intends to inherit. It does so in a **class derivation list**, which is a colon followed by a comma-separated list of base classes each of which may have an optional access specifier:

Because Bulk_quote uses public in its derivation list, we can use objects of type Bulk_quote as if they were Quote objects.

A derived class must include in its own class body a declaration of all the virtual functions it intends to define for itself. A derived class may include the virtual keyword on these functions but is not required to do so. For reasons we'll explain in § 15.3 (p. 606), the new standard lets a derived class explicitly note that it intends a member function to **override** a virtual that it inherits. It does so by specifying override after its parameter list.

Dynamic Binding

Through **dynamic binding**, we can use the same code to process objects of either type Quote or Bulk_quote interchangeably. For example, the following function prints the total price for purchasing the given number of copies of a given book:

Click here to view code image

This function is pretty simple—it prints the results of calling isbn and net_price on its parameter and returns the value calculated by the call to net_price.

Nevertheless, there are two interesting things about this function: For reasons we'll explain in § 15.2.3 (p. 601), because the item parameter is a reference to Quote, we can call this function on either a Quote object or a Bulk_quote object. And, for reasons we'll explain in § 15.2.1 (p. 594), because net_price is a virtual function, and because print_total calls net_price through a reference, the version of net_price that is run will depend on the type of the object that we pass to print_total:

Click here to view code image

```
// basic has type Quote; bulk has type Bulk_quote
print_total(cout, basic, 20); // calls Quote version of net_price
print_total(cout, bulk, 20); // calls Bulk_quote version of net_price
```

The first call passes a Quote object to print_total. When print_total calls net_price, the Quote version will be run. In the next call, the argument is a

Bulk_quote, so the Bulk_quote version of net_price (which applies a discount) will be run. Because the decision as to which version to run depends on the type of the argument, that decision can't be made until run time. Therefore, dynamic binding is sometimes known as run-time binding.

Note

In C++, dynamic binding happens when a virtual function is called through a reference (or a pointer) to a base class.

15.2. Defining Base and Derived Classes

In many, but not all, ways base and derived classes are defined like other classes we have already seen. In this section, we'll cover the basic features used to define classes related by inheritance.

15.2.1. Defining a Base Class

We'll start by completing the definition of our Quote class:

Click here to view code image

The new parts in this class are the use of virtual on the net_price function and the destructor, and the protected access specifier. We'll explain virtual destructors in §15.7.1 (p. 622), but for now it is worth noting that classes used as the root of an inheritance hierarchy almost always define a virtual destructor.

Base classes ordinarily should define a virtual destructor. Virtual destructors are needed even if they do no work.

Member Functions and Inheritance

Derived classes inherit the members of their base class. However, a derived class needs to be able to provide its own definition for operations, such as net_price, that are type dependent. In such cases, the derived class needs to **override** the definition it inherits from the base class, by providing its own definition.

In C++, a base class must distinguish the functions it expects its derived classes to override from those that it expects its derived classes to inherit without change. The base class defines as **virtual** those functions it expects its derived classes to override. When we call a virtual function through a pointer or reference, the call will be dynamically bound. Depending on the type of the object to which the reference or pointer is bound, the version in the base class or in one of its derived classes will be executed.

A base class specifies that a member function should be dynamically bound by preceding its declaration with the keyword virtual. Any nonstatic member function (§7.6, p. 300), other than a constructor, may be virtual. The virtual keyword appears only on the declaration inside the class and may not be used on a function definition that appears outside the class body. A function that is declared as virtual in the base class is implicitly virtual in the derived classes as well. We'll have more to say about virtual functions in §15.3 (p. 603).

Member functions that are not declared as <code>virtual</code> are resolved at compile time, not run time. For the <code>isbn</code> member, this is exactly the behavior we want. The <code>isbn</code> function does not depend on the details of a derived type. It behaves identically when run on a <code>Quote</code> or <code>Bulk_quote</code> object. There will be only one version of the <code>isbn</code> function in our inheritance hierarchy. Thus, there is no question as to which function to run when we call <code>isbn()</code>.

Access Control and Inheritance

A derived class inherits the members defined in its base class. However, the member functions in a derived class may not necessarily access the members that are inherited from the base class. Like any other code that uses the base class, a derived class may access the public members of its base class but may not access the private members. However, sometimes a base class has members that it wants to let its derived classes use while still prohibiting access to those same members by other

users. We specify such members after a protected access specifier.

Our Quote class expects its derived classes to define their own net_price function. To do so, those classes need access to the price member. As a result, Quote defines that member as protected. Derived classes are expected to access bookNo in the same way as ordinary users—by calling the isbn function. Hence, the bookNo member is private and is inaccessible to classes that inherit from Quote. We'll have more to say about protected members in §15.5 (p. 611).

Exercises Section 15.2.1

Exercise 15.1: What is a virtual member?

Exercise 15.2: How does the protected access specifier differ from private?

Exercise 15.3: Define your own versions of the Quote class and the print_total function.

15.2.2. Defining a Derived Class

A derived class must specify from which class(es) it inherits. It does so in its **class derivation list**, which is a colon followed by a comma-separated list of names of previously defined classes. Each base class name may be preceded by an optional access specifier, which is one of public, protected, or private.

A derived class must declare each inherited member function it intends to override. Therefore, our Bulk_quote class must include a net_price member:

Click here to view code image

Our Bulk_quote class inherits the isbn function and the bookNo and price data members of its Quote base class. It defines its own version of net_price and has

two additional data members, min_qty and discount. These members specify the minimum quantity and the discount to apply once that number of copies are purchased.

We'll have more to say about the access specifier used in a derivation list in §15.5 (p. 612). For now, what's useful to know is that the access specifier determines whether users of a derived class are allowed to know that the derived class inherits from its base class.

When the derivation is public, the public members of the base class become part of the interface of the derived class as well. In addition, we can bind an object of a publicly derived type to a pointer or reference to the base type. Because we used public in the derivation list, the interface to Bulk_quote implicitly contains the isbn function, and we may use a Bulk_quote object where a pointer or reference to Quote is expected.

Most classes inherit directly from only one base class. This form of inheritance, known as "single inheritance," forms the topic of this chapter. §18.3 (p. 802) will cover classes that have derivation lists with more than one base class.

Virtual Functions in the Derived Class

Derived classes frequently, but not always, override the virtual functions that they inherit. If a derived class does not override a virtual from its base, then, like any other member, the derived class inherits the version defined in its base class.

A derived class may include the virtual keyword on the functions it overrides, but it is not required to do so. For reasons we'll explain in §15.3 (p. 606), the new standard lets a derived class explicitly note that it intends a member function to override a virtual that it inherits. It does so by specifying override after the parameter list, or after the const or reference qualifier(s) if the member is a const (§7.1.2, p. 258) or reference (§13.6.3, p. 546) function.

Derived-Class Objects and the Derived-to-Base Conversion

A derived object contains multiple parts: a subobject containing the (nonstatic) members defined in the derived class itself, plus subobjects corresponding to each base class from which the derived class inherits. Thus, a Bulk_quote object will contain four data elements: the bookNo and price data members that it inherits from Quote, and the min_qty and discount members, which are defined by Bulk_quote.

Although the standard does not specify how derived objects are laid out in memory, we can think of a Bulk_quote object as consisting of two parts as represented in Figure 15.1.

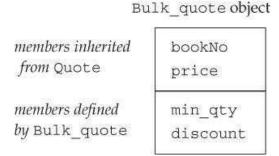

Figure 15.1. Conceptual Structure of a Bulk_quote Object

The base and derived parts of an object are not guaranteed to be stored contiguously. Figure 15.1 is a conceptual, not physical, representation of how classes work.

Because a derived object contains subparts corresponding to its base class(es), we can use an object of a derived type as if it were an object of its base type(s). In particular, we can bind a base-class reference or pointer to the base-class part of a derived object.

Click here to view code image

```
Quote item;
                           object of base type
Bulk_quote bulk;
                      //
                           object of derived type
Quote *p = &item;
                      // p points to a Quote object
p = &bulk;
                      //
                           p points to the Quote part of bulk
Quote &r = bulk;
                      // r bound to the Quote part of bulk
```

This conversion is often referred to as the derived-to-base conversion. As with any other conversion, the compiler will apply the derived-to-base conversion implicitly (§4.11, p. 159).

The fact that the derived-to-base conversion is implicit means that we can use an object of derived type or a reference to a derived type when a reference to the base type is required. Similarly, we can use a pointer to a derived type where a pointer to the base type is required.

The fact that a derived object contains subobjects for its base classes is key to how inheritance works.

Derived-Class Constructors

Although a derived object contains members that it inherits from its base, it cannot

directly initialize those members. Like any other code that creates an object of the base-class type, a derived class must use a base-class constructor to initialize its base-class part.

Note

Each class controls how its members are initialized.

The base-class part of an object is initialized, along with the data members of the derived class, during the initialization phase of the constructor (§7.5.1, p. 288). Analogously to how we initialize a member, a derived-class constructor uses its constructor initializer list to pass arguments to a base-class constructor. For example, the Bulk_quote constructor with four parameters:

Click here to view code image

passes its first two parameters (representing the ISBN and price) to the Quote constructor. That Quote constructor initializes the Bulk_quote's base-class part (i.e., the bookNo and price members). When the (empty) Quote constructor body completes, the base-class part of the object being constructed will have been initialized. Next the direct members, min_qty and discount, are initialized. Finally, the (empty) function body of the Bulk_quote constructor is run.

As with a data member, unless we say otherwise, the base part of a derived object is default initialized. To use a different base-class constructor, we provide a constructor initializer using the name of the base class, followed (as usual) by a parenthesized list of arguments. Those arguments are used to select which base-class constructor to use to initialize the base-class part of the derived object.

Note

The base class is initialized first, and then the members of the derived class are initialized in the order in which they are declared in the class.

Using Members of the Base Class from the Derived Class

A derived class may access the public and protected members of its base class:

Click here to view code image

```
// if the specified number of items are purchased, use the discounted price
double Bulk_quote::net_price(size_t cnt) const
{
    if (cnt >= min_qty)
        return cnt * (1 - discount) * price;
    else
        return cnt * price;
}
```

This function generates a discounted price: If the given quantity is more than min_qty, we apply the discount (which was stored as a fraction) to the price.

We'll have more to say about scope in §15.6 (p. 617), but for now it's worth knowing that the scope of a derived class is nested inside the scope of its base class. As a result, there is no distinction between how a member of the derived class uses members defined in its own class (e.g., min_qty and discount) and how it uses members defined in its base (e.g., price).

Key Concept: Respecting the Base-Class Interface

It is essential to understand that each class defines its own interface. Interactions with an object of a class-type should use the interface of that class, even if that object is the base-class part of a derived object.

As a result, derived-class constructors may not directly initialize the members of its base class. The constructor body of a derived constructor can assign values to its public or protected base-class members. Although it can assign to those members, it generally should not do so. Like any other user of the base class, a derived class should respect the interface of its base class by using a constructor to initialize its inherited members.

Inheritance and static Members

If a base class defines a static member (§7.6, p. 300), there is only one such member defined for the entire hierarchy. Regardless of the number of classes derived from a base class, there exists a single instance of each static member.

```
class Base {
public:
    static void statmem();
};
class Derived : public Base {
    void f(const Derived&);
};
```

static members obey normal access control. If the member is private in the base class, then derived classes have no access to it. Assuming the member is accessible, we can use a static member through either the base or derived:

Click here to view code image

Declarations of Derived Classes

A derived class is declared like any other class (§7.3.3, p. 278). The declaration contains the class name but does not include its derivation list:

Click here to view code image

```
class Bulk_quote : public Quote; // error: derivation list can't appear
here
class Bulk_quote; // ok: right way to declare a derived
class
```

The purpose of a declaration is to make known that a name exists and what kind of entity it denotes, for example, a class, function, or variable. The derivation list, and all other details of the definition, must appear together in the class body.

Classes Used as a Base Class

A class must be defined, not just declared, before we can use it as a base class:

Click here to view code image

```
class Quote;  // declared but not defined
// error: Quote must be defined
class Bulk_quote : public Quote { ... };
```

The reason for this restriction should be easy to see: Each derived class contains, and may use, the members it inherits from its base class. To use those members, the derived class must know what they are. One implication of this rule is that it is impossible to derive a class from itself.

A base class can itself be a derived class:

```
class Base { /* ... */ };
class D1: public Base { /* ... */ };
class D2: public D1 { /* ... */ };
```

In this hierarchy, Base is a **direct base** to D1 and an **indirect base** to D2. A direct base class is named in the derivation list. An indirect base is one that a derived class inherits through its direct base class.

Each class inherits all the members of its direct base class. The most derived class inherits the members of its direct base. The members in the direct base include those it inherits from its base class, and so on up the inheritance chain. Effectively, the most derived object contains a subobject for its direct base and for each of its indirect bases.

Preventing Inheritance

Sometimes we define a class that we don't want others to inherit from. Or we might define a class for which we don't want to think about whether it is appropriate as a base class. Under the new standard, we can prevent a class from being used as a base by following the class name with final:

Click here to view code image

```
class NoDerived final { /* */ }; // NoDerived can't be a base class
class Base { /* */ };
// Last is final; we cannot inherit from Last
class Last final : Base { /* */ }; // Last can't be a base class
class Bad : NoDerived { /* */ }; // error: NoDerived is final
class Bad2 : Last { /* */ }; // error: Last is final
```

Exercises Section 15.2.2

Exercise 15.4: Which of the following declarations, if any, are incorrect? Explain why.

```
class Base { ... };
(a) class Derived : public Derived { ... };
(b) class Derived : private Base { ... };
(c) class Derived : public Base;
```

Exercise 15.5: Define your own version of the Bulk_quote class.

Exercise 15.6: Test your print_total function from the exercises in § 15.2.1 (p. 595) by passing both Quote and Bulk_quote objects o that function.

Exercise 15.7: Define a class that implements a limited discount strategy, which applies a discount to books purchased up to a given limit. If the number of copies exceeds that limit, the normal price applies to those purchased beyond the limit.

15.2.3. Conversions and Inheritance

🗥 Warning

Understanding conversions between base and derived classes is essential to understanding how object-oriented programming works in C++.

Ordinarily, we can bind a reference or a pointer only to an object that has the same type as the corresponding reference or pointer (§2.3.1, p. 51, and §2.3.2, p. 52) or to a type that involves an acceptable const conversion (§4.11.2, p. 162). Classes related by inheritance are an important exception: We can bind a pointer or reference to a base-class type to an object of a type derived from that base class. For example, we can use a Quote& to refer to a Bulk_quote object, and we can assign the address of a Bulk quote object to a Quote*.

The fact that we can bind a reference (or pointer) to a base-class type to a derived object has a crucially important implication: When we use a reference (or pointer) to a base-class type, we don't know the actual type of the object to which the pointer or reference is bound. That object can be an object of the base class or it can be an object of a derived class.

Note

Like built-in pointers, the smart pointer classes (§12.1, p. 450) support the derived-to-base conversion—we can store a pointer to a derived object in a smart pointer to the base type.

Static Type and Dynamic Type

When we use types related by inheritance, we often need to distinguish between the static type of a variable or other expression and the dynamic type of the object that expression represents. The static type of an expression is always known at

compile time—it is the type with which a variable is declared or that an expression yields. The dynamic type is the type of the object in memory that the variable or expression represents. The dynamic type may not be known until run time.

```
For example, when print_total calls net_price (§15.1, p. 593):
 double ret = item.net price(n);
```

we know that the static type of item is Quote&. The dynamic type depends on the type of the argument to which item is bound. That type cannot be known until a call is executed at run time. If we pass a Bulk_quote object to print_total, then the static type of item will differ from its dynamic type. As we've seen, the static type of item is Quote&, but in this case the dynamic type is Bulk_quote.

The dynamic type of an expression that is neither a reference nor a pointer is always the same as that expression's static type. For example, a variable of type Quote is always a Quote object; there is nothing we can do that will change the type of the object to which that variable corresponds.

It is crucial to understand that the static type of a pointer or reference to a base class may differ from its dynamic type.

There Is No Implicit Conversion from Base to Derived ...

The conversion from derived to base exists because every derived object contains a base-class part to which a pointer or reference of the base-class type can be bound. There is no similar guarantee for base-class objects. A base-class object can exist either as an independent object or as part of a derived object. A base object that is not part of a derived object has only the members defined by the base class; it doesn't have the members defined by the derived class.

Because a base object might or might not be part of a derived object, there is no automatic conversion from the base class to its derived class(s):

Click here to view code image

```
Quote base;
Bulk quote* bulkP = &base; // error: can't convert base to derived
Bulk quote& bulkRef = base; // error: can't convert base to derived
```

If these assignments were legal, we might attempt to use bulkP or bulkRef to use members that do not exist in base.

What is sometimes a bit surprising is that we cannot convert from base to derived even when a base pointer or reference is bound to a derived object:

Click here to view code image

The compiler has no way to know (at compile time) that a specific conversion will be safe at run time. The compiler looks only at the static types of the pointer or reference to determine whether a conversion is legal. If the base class has one or more virtual functions, we can use a dynamic_cast (which we'll cover in §19.2.1 (p. 825)) to request a conversion that is checked at run time. Alternatively, in those cases when we know that the conversion from base to derived is safe, we can use a static_cast (§4.11.3, p. 162) to override the compiler.

...and No Conversion between Objects

The automatic derived-to-base conversion applies only for conversions to a reference or pointer type. There is no such conversion from a derived-class type to the base-class type. Nevertheless, it is often possible to convert an object of a derived class to its base-class type. However, such conversions may not behave as we might want.

Remember that when we initialize or assign an object of a class type, we are actually calling a function. When we initialize, we're calling a constructor (§13.1.1, p. 496, and §13.6.2, p. 534); when we assign, we're calling an assignment operator (§13.1.2, p. 500, and §13.6.2, p. 536). These members normally have a parameter that is a reference to the const version of the class type.

Because these members take references, the derived-to-base conversion lets us pass a derived object to a base-class copy/move operation. These operations are not virtual. When we pass a derived object to a base-class constructor, the constructor that is run is defined in the base class. That constructor knows *only* about the members of the base class itself. Similarly, if we assign a derived object to a base object, the assignment operator that is run is the one defined in the base class. That operator also knows *only* about the members of the base class itself.

For example, our bookstore classes use the synthesized versions of copy and assignment (§13.1.1, p. 497, and §13.1.2, p. 500). We'll have more to say about copy control and inheritance in §15.7.2 (p. 623), but for now what's useful to know is that the synthesized versions memberwise copy or assign the data members of the class the same way as for any other class:

```
Bulk_quote bulk;  // object of derived type
Quote item(bulk);  // uses the Quote::Quote(const Quote&) constructor
item = bulk;  // calls Quote::operator=(const Quote&)
```

When item is constructed, the Quote copy constructor is run. That constructor knows only about the bookNo and price members. It copies those members from the Quote part of bulk and ignores the members that are part of the Bulk quote portion of bulk. Similarly for the assignment of bulk to item; only the Quote part of bulk is assigned to item.

Because the Bulk_quote part is ignored, we say that the Bulk_quote portion of bulk is **sliced down**.

Warning

When we initialize or assign an object of a base type from an object of a derived type, only the base-class part of the derived object is copied, moved, or assigned. The derived part of the object is ignored.

15.3. Virtual Functions

As we've seen, in C++ dynamic binding happens when a virtual member function is called through a reference or a pointer to a base-class type (§15.1, p. 593). Because we don't know which version of a function is called until run time, virtual functions must always be defined. Ordinarily, if we do not use a function, we don't need to supply a definition for that function (§6.1.2, p. 206). However, we must define every virtual function, regardless of whether it is used, because the compiler has no way to determine whether a virtual function is used.

Exercises Section 15.2.3

Exercise 15.8: Define static type and dynamic type.

Exercise 15.9: When is it possible for an expression's static type to differ from its dynamic type? Give three examples in which the static and dynamic type differ.

Exercise 15.10: Recalling the discussion from §8.1 (p. 311), explain how the program on page 317 that passed an ifstream to the Sales_data read function works.

Key Concept: Conversions among Types Related by Inheritance

There are three things that are important to understand about conversions among classes related by inheritance:

• The conversion from derived to base applies only to pointer or reference

types.

- There is no implicit conversion from the base-class type to the derived type.
- Like any member, the derived-to-base conversion may be inaccessible due to access controls. We'll cover accessibility in §15.5 (p. 613).

Although the automatic conversion applies only to pointers and references, most classes in an inheritance hierarchy (implicitly or explicitly) define the copy-control members (Chapter 13). As a result, we can often copy, move, or assign an object of derived type to a base-type object. However, copying, moving, or assigning a derived-type object to a base-type object copies, moves, or assigns only the members in the base-class part of the object.

Calls to Virtual Functions May Be Resolved at Run Time

When a virtual function is called through a reference or pointer, the compiler generates code to *decide at run time* which function to call. The function that is called is the one that corresponds to the dynamic type of the object bound to that pointer or reference.

As an example, consider our print_total function from §15.1 (p. 593). That function calls net_price on its parameter named item, which has type Quote&. Because item is a reference, and because net_price is virtual, the version of net_price that is called depends at run time on the actual (dynamic) type of the argument bound to item:

Click here to view code image

```
Quote base("0-201-82470-1", 50);
print_total(cout, base, 10); // calls Quote::net_price
Bulk_quote derived("0-201-82470-1", 50, 5, .19);
print_total(cout, derived, 10); // calls Bulk_quote::net_price
```

In the first call, item is bound to an object of type Quote. As a result, when print_total calls net_price, the version defined by Quote is run. In the second call, item is bound to a Bulk_quote object. In this call, print_total calls the Bulk_quote version of net_price.

It is crucial to understand that dynamic binding happens only when a virtual function is called through a pointer or a reference.

Click here to view code image

When we call a virtual function on an expression that has a plain—nonreference and

nonpointer—type, that call is bound at compile time. For example, when we call net_price on base, there is no question as to which version of net_price to run. We can change the value (i.e., the contents) of the object that base represents, but there is no way to change the type of that object. Hence, this call is resolved, at compile time, to the Quote version of net_price.

Key Concept: Polymorphism in C++

The key idea behind OOP is polymorphism. Polymorphism is derived from a Greek word meaning "many forms." We speak of types related by inheritance as polymorphic types, because we can use the "many forms" of these types while ignoring the differences among them. The fact that the static and dynamic types of references and pointers can differ is the cornerstone of how C++ supports polymorphism.

When we call a function defined in a base class through a reference or pointer to the base class, we do not know the type of the object on which that member is executed. The object can be a base-class object or an object of a derived class. If the function is virtual, then the decision as to which function to run is delayed until run time. The version of the virtual function that is run is the one defined by the type of the object to which the reference is bound or to which the pointer points.

On the other hand, calls to nonvirtual functions are bound at compile time. Similarly, calls to any function (virtual or not) on an object are also bound at compile time. The type of an object is fixed and unvarying—there is nothing we can do to make the dynamic type of an object differ from its static type. Therefore, calls made on an object are bound at compile time to the version defined by the type of the object.

Note

Virtuals are resolved at run time *only* if the call is made through a reference or pointer. Only in these cases is it possible for an object's dynamic type to differ from its static type.

Virtual Functions in a Derived Class

When a derived class overrides a virtual function, it may, but is not required to, repeat the virtual keyword. Once a function is declared as virtual, it remains virtual in all the derived classes.

A derived-class function that overrides an inherited virtual function must have

exactly the same parameter type(s) as the base-class function that it overrides.

With one exception, the return type of a virtual in the derived class also must match the return type of the function from the base class. The exception applies to virtuals that return a reference (or pointer) to types that are themselves related by inheritance. That is, if D is derived from B, then a base class virtual can return a B* and the version in the derived can return a D*. However, such return types require that the derived-to-base conversion from D to B is accessible. §15.5 (p. 613) covers how to determine whether a base class is accessible. We'll see an example of this kind of virtual function in §15.8.1 (p. 633).

A function that is virtual in a base class is implicitly virtual in its derived classes. When a derived class overrides a virtual, the parameters in the base and derived classes must match exactly.

The final and override Specifiers

As we'll see in §15.6 (p. 620), it is legal for a derived class to define a function with the same name as a virtual in its base class but with a different parameter list. The compiler considers such a function to be independent from the base-class function. In such cases, the derived version does not override the version in the base class. In practice, such declarations often are a mistake—the class author intended to override a virtual from the base class but made a mistake in specifying the parameter list. C++

Finding such bugs can be surprisingly hard. Under the new standard we can specify override on a virtual function in a derived class. Doing so makes our intention clear and (more importantly) enlists the compiler in finding such problems for us. The compiler will reject a program if a function marked override does not override an existing virtual function:

```
struct B {
    virtual void f1(int) const;
    virtual void f2();
    void f3();
};
struct D1 : B {
    void f1(int) const override; // ok: f1 matches f1 in the base
    void f2(int) override; // error: B has no f2(int) function
    void f3() override;
                              // error: f3 not virtual
                              // error: B doesn't have a function named f4
    void f4() override;
```

};

In D1, the override specifier on f1 is fine; both the base and derived versions of f1 are const members that take an int and return void. The version of f1 in D1 properly overrides the virtual that it inherits from B.

The declaration of £2 in D1 does not match the declaration of £2 in B—the version defined in B takes no arguments and the one defined in D1 takes an int. Because the declarations don't match, £2 in D1 doesn't override £2 from B; it is a new function that happens to have the same name. Because we said we intended this declaration to be an override and it isn't, the compiler will generate an error.

Because only a virtual function can be overridden, the compiler will also reject £3 in D1. That function is not virtual in B, so there is no function to override. Similarly £4 is in error because B doesn't even have a function named £4.

We can also designate a function as final. Any attempt to override a function that has been defined as final will be flagged as an error:

Click here to view code image

final and override specifiers appear after the parameter list (including any const or reference qualifiers) and after a trailing return (§ 6.3.3, p. 229).

Virtual Functions and Default Arguments

Like any other function, a virtual function can have default arguments (§ 6.5.1, p. 236). If a call uses a default argument, the value that is used is the one defined by the static type through which the function is called.

That is, when a call is made through a reference or pointer to base, the default argument(s) will be those defined in the base class. The base-class arguments will be used even when the derived version of the function is run. In this case, the derived function will be passed the default arguments defined for the base-class version of the function. If the derived function relies on being passed different arguments, the program will not execute as expected.

Virtual functions that have default arguments should use the same argument values in the base and derived classes.

Circumventing the Virtual Mechanism

In some cases, we want to prevent dynamic binding of a call to a virtual function; we want to force the call to use a particular version of that virtual. We can use the scope operator to do so. For example, this code:

Click here to view code image

// calls the version from the base class regardless of the dynamic type of baseP double undiscounted = baseP->Quote::net price(42);

calls the Quote version of net_price regardless of the type of the object to which baseP actually points. This call will be resolved at compile time.

Note

Ordinarily, only code inside member functions (or friends) should need to use the scope operator to circumvent the virtual mechanism.

Why might we wish to circumvent the virtual mechanism? The most common reason is when a derived-class virtual function calls the version from the base class. In such cases, the base-class version might do work common to all types in the hierarchy. The versions defined in the derived classes would do whatever additional work is particular to their own type.

Warning

If a derived virtual function that intended to call its base-class version omits the scope operator, the call will be resolved at run time as a call to the derived version itself, resulting in an infinite recursion.

Exercises Section 15.3

Exercise 15.11: Add a virtual debug function to your Quote class hierarchy that displays the data members of the respective classes.

Exercise 15.12: Is it ever useful to declare a member function as both override and final? Why or why not?

Exercise 15.13: Given the following classes, explain each print function:

Click here to view code image

```
class base {
public:
    string name() { return basename; }
    virtual void print(ostream &os) { os << basename; }
private:
    string basename;
};
class derived : public base {
public:
    void print(ostream &os) { print(os); os << " " << i; }
private:
    int i;
};</pre>
```

If there is a problem in this code, how would you fix it?

Exercise 15.14: Given the classes from the previous exercise and the following objects, determine which function is called at run time:

Click here to view code image

```
base bobj; base *bp1 = &bobj; base &br1 = bobj;
derived dobj; base *bp2 = &dobj; base &br2 = dobj;

(a) bobj.print();
(b) dobj.print();
(c) bp1->name();
(d) bp2->name();
(e) br1.print();
(f) br2.print();
```

15.4. Abstract Base Classes

Imagine that we want to extend our bookstore classes to support several discount strategies. In addition to a bulk discount, we might offer a discount for purchases up to a certain quantity and then charge the full price thereafter. Or we might offer a discount for purchases above a certain limit but not for purchases up to that limit.

Each of these discount strategies is the same in that it requires a quantity and a discount amount. We might support these differing strategies by defining a new class named <code>Disc_quote</code> to store the quantity and the discount amount. Classes, such as <code>Bulk_item</code>, that represent a specific discount strategy will inherit from <code>Disc_quote</code>. Each of the derived classes will implement its discount strategy by defining its own

version of net_price.

Before we can define our Disc_Quote class, we have to decide what to do about net_price. Our Disc_quote class doesn't correspond to any particular discount strategy; there is no meaning to ascribe to net_price for this class.

We could define Disc_quote without its own version of net_price. In this case, Disc_quote would inherit net_price from Quote.

However, this design would make it possible for our users to write nonsensical code. A user could create an object of type <code>Disc_quote</code> by supplying a quantity and a discount rate. Passing that <code>Disc_quote</code> object to a function such as <code>print_total</code> would use the <code>Quote</code> version of <code>net_price</code>. The calculated price would not include the discount that was supplied when the object was created. That state of affairs makes no sense.

Pure Virtual Functions

Thinking about the question in this detail reveals that our problem is not just that we don't know how to define net_price. In practice, we'd like to prevent users from creating Disc_quote objects at all. This class represents the general concept of a discounted book, not a concrete discount strategy.

We can enforce this design intent—and make it clear that there is no meaning for net_price—by defining net_price as a pure virtual function. Unlike ordinary virtuals, a pure virtual function does not have to be defined. We specify that a virtual function is a pure virtual by writing = 0 in place of a function body (i.e., just before the semicolon that ends the declaration). The = 0 may appear only on the declaration of a virtual function in the class body:

Click here to view code image

```
// class to hold the discount rate and quantity
// derived classes will implement pricing strategies using these data
class Disc_quote : public Quote {
public:
    Disc quote() = default;
    Disc quote(const std::string& book, double price,
                std::size_t qty, double disc):
                    Quote(book, price),
                   quantity(qty), discount(disc) { }
    double net_price(std::size_t) const = 0;
protected:
    std::size_t quantity = 0; // purchase size for the discount to apply
    double discount = 0.0;
                                  //
                                      fractional discount to apply
};
```

Like our earlier Bulk_item class, Disc_quote defines a default constructor and a constructor that takes four parameters. Although we cannot define objects of this type directly, constructors in classes derived from Disc_quote will use the Disc_quote

constructors to construct the Disc quote part of their objects. The constructor that has four parameters passes its first two to the Quote constructor and directly initializes its own members, discount and quantity. The default constructor default initializes those members.

It is worth noting that we can provide a definition for a pure virtual. However, the function body must be defined outside the class. That is, we cannot provide a function body inside the class for a function that is = 0.

Classes with Pure Virtuals Are Abstract Base Classes

A class containing (or inheriting without overridding) a pure virtual function is an abstract base class. An abstract base class defines an interface for subsequent classes to override. We cannot (directly) create objects of a type that is an abstract base class. Because Disc_quote defines net_price as a pure virtual, we cannot define objects of type Disc_quote. We can define objects of classes that inherit from Disc_quote, so long as those classes override net_price:

Click here to view code image

```
// Disc_quote declares pure virtual functions, which Bulk_quote will override
Disc_quote discounted; // error: can't define a Disc_quote object
Bulk_quote bulk;
                              // ok: Bulk_quote has no pure virtual functions
```

Classes that inherit from Disc quote must define net price or those classes will be abstract as well.

We may not create objects of a type that is an abstract base class.

A Derived Class Constructor Initializes Its Direct Base Class Only

Now we can reimplement Bulk quote to inherit from Disc quote rather than inheriting directly from Quote:

```
// the discount kicks in when a specified number of copies of the same book are sold
// the discount is expressed as a fraction to use to reduce the normal price
class Bulk_quote : public Disc_quote {
public:
    Bulk quote() = default;
     Bulk quote(const std::string& book, double price,
                 std::size_t qty, double disc):
            Disc_quote(book, price, qty, disc) { }
```

```
// overrides the base version to implement the bulk purchase discount policy
double net_price(std::size_t) const override;
};
```

This version of Bulk_quote has a direct base class, Disc_quote, and an indirect base class, Quote. Each Bulk_quote object has three subobjects: an (empty) Bulk_quote part, a Disc_quote subobject, and a Quote subobject.

As we've seen, each class controls the initialization of objects of its type. Therefore, even though <code>Bulk_quote</code> has no data members of its own, it provides the same four-argument constructor as in our original class. Our new constructor passes its arguments to the <code>Disc_quote</code> constructor. That constructor in turn runs the <code>Quote</code> constructor. The <code>Quote</code> constructor initializes the <code>bookNo</code> and <code>price</code> members of <code>bulk</code>. When the <code>Quote</code> constructor ends, the <code>Disc_quote</code> constructor runs and initializes the <code>quantity</code> and <code>discount</code> members. At this point, the <code>Bulk_quote</code> constructor resumes. That constructor has no further initializations or any other work to do.

Key Concept: Refactoring

Adding Disc_quote to the Quote hierarchy is an example of *refactoring*. Refactoring involves redesigning a class hierarchy to move operations and/or data from one class to another. Refactoring is common in object-oriented applications.

It is noteworthy that even though we changed the inheritance hierarchy, code that uses Bulk_quote or Quote would not need to change. However, when classes are refactored (or changed in any other way) we must recompile any code that uses those classes.

Exercises Section 15.4

Exercise 15.15: Define your own versions of Disc_quote and Bulk_quote.

Exercise 15.16: Rewrite the class representing a limited discount strategy, which you wrote for the exercises in § 15.2.2 (p. 601), to inherit from Disc_quote.

Exercise 15.17: Try to define an object of type Disc_quote and see what errors you get from the compiler.

15.5. Access Control and Inheritance

Just as each class controls the initialization of its own members (§ 15.2.2, p. 598), each class also controls whether its members are **accessible** to a derived class.

protected Members

As we've seen, a class uses protected for those members that it is willing to share with its derived classes but wants to protect from general access. The protected specifier can be thought of as a blend of private and public:

- Like private, protected members are inaccessible to users of the class.
- Like public, protected members are accessible to members and friends of classes derived from this class.

In addition, protected has another important property:

• A derived class member or friend may access the protected members of the base class only through a derived object. The derived class has no special access to the protected members of base-class objects.

To understand this last rule, consider the following example:

Click here to view code image

If derived classes (and friends) could access protected members in a base-class object, then our second version of clobber (that takes a Base&) would be legal. That function is not a friend of Base, yet it would be allowed to change an object of type Base; we could circumvent the protection provided by protected for any class simply by defining a new class along the lines of Sneaky.

To prevent such usage, members and friends of a derived class can access the protected members *only* in base-class objects that are embedded inside a derived type object; they have no special access to ordinary objects of the base type.

public, private, and protected Inheritance

Access to a member that a class inherits is controlled by a combination of the access specifier for that member in the base class, and the access specifier in the derivation list of the derived class. As an example, consider the following hierarchy:

Click here to view code image

```
class Base {
public:
    void pub_mem(); // public member
protected:
    int prot_mem;
                         // protected member
private:
    char priv_mem; // private member
};
struct Pub_Derv : public Base {
    // ok: derived classes can access protected members
    int f() { return prot_mem; }
    // error: private members are inaccessible to derived classes
    char g() { return priv_mem; }
};
struct Priv_Derv : private Base {
    // private derivation doesn't affect access in the derived class
    int f1() const { return prot_mem; }
};
```

The derivation access specifier has no effect on whether members (and friends) of a derived class may access the members of its own direct base class. Access to the members of a base class is controlled by the access specifiers in the base class itself. Both Pub_Derv and Priv_Derv may access the protected member prot_mem. Neither may access the private member priv_mem.

The purpose of the derivation access specifier is to control the access that users of the derived class—including other classes derived from the derived class—have to the members inherited from Base:

Click here to view code image

```
Pub_Derv d1; // members inherited from Base are public

Priv_Derv d2; // members inherited from Base are private

d1.pub_mem(); // ok: pub_mem is public in the derived class

d2.pub mem(); // error: pub mem is private in the derived class
```

Both Pub_Derv and Priv_Derv inherit the pub_mem function. When the inheritance is public, members retain their access specification. Thus, d1 can call pub_mem. In Priv_Derv, the members of Base are private; users of that class may not call pub_mem.

The derivation access specifier used by a derived class also controls access from classes that inherit from that derived class:

Click here to view code image

```
struct Derived from Public : public Pub Derv {
    // ok: Base::prot_mem remains protected in Pub_Derv
    int use_base() { return prot_mem; }
};
struct Derived from Private : public Priv Derv {
    // error: Base::prot_mem is private in Priv_Derv
    int use_base() { return prot_mem; }
};
```

Classes derived from Pub_Derv may access prot_mem from Base because that member remains a protected member in Pub Derv. In contrast, classes derived from Priv Derv have no such access. To them, all the members that Priv Derv inherited from Base are private.

Had we defined another class, say, Prot_Derv, that used protected inheritance, the public members of Base would be protected members in that class. Users of Prot Derv would have no access to pub mem, but the members and friends of Prot Derv could access that inherited member.

Accessibility of Derived-to-Base Conversion

Whether the derived-to-base conversion (§ 15.2.2, p. 597) is accessible depends on which code is trying to use the conversion and may depend on the access specifier used in the derived class' derivation. Assuming D inherits from B:

- User code may use the derived-to-base conversion only if D inherits publicly from B. User code may not use the conversion if D inherits from B using either protected Or private.
- Member functions and friends of D can use the conversion to B regardless of how D inherits from B. The derived-to-base conversion to a direct base class is always accessible to members and friends of a derived class.
- Member functions and friends of classes derived from D may use the derived-tobase conversion if D inherits from B using either public or protected. Such code may not use the conversion if D inherits privately from B.

For any given point in your code, if a public member of the base class would be accessible, then the derived-to-base conversion is also accessible, and not otherwise.

In the absence of inheritance, we can think of a class as having two different kinds of users: ordinary users and implementors. Ordinary users write code that uses objects of the class type; such code can access only the public (interface) members of the class. Implementors write the code contained in the members and friends of the class. The members and friends of the class can access both the public and private (implementation) sections.

Under inheritance, there is a third kind of user, namely, derived classes. A base class makes protected those parts of its implementation that it is willing to let its derived classes use. The protected members remain inaccessible to ordinary user code; private members remain inaccessible to derived classes and their friends.

Like any other class, a class that is used as a base class makes its interface members public. A class that is used as a base class may divide its implementation into those members that are accessible to derived classes and those that remain accessible only to the base class and its friends. An implementation member should be protected if it provides an operation or data that a derived class will need to use in its own implementation. Otherwise, implementation members should be private.

Friendship and Inheritance

Just as friendship is not transitive (§7.3.4, p. 279), friendship is also not inherited. Friends of the base have no special access to members of its derived classes, and friends of a derived class have no special access to the base class:

Click here to view code image

```
class Base {
    // added friend declaration; other members as before
    friend class Pal; // Pal has no access to classes derived from Base
};
class Pal {
public:
    int f(Base b) { return b.prot_mem; } // ok: Pal is a friend of
Base
    int f2(Sneaky s) { return s.j; } // error: Pal not friend of
Sneaky
    // access to a base class is controlled by the base class, even inside a derived
object
    int f3(Sneaky s) { return s.prot_mem; } // ok: Pal is a friend
};
```

The fact that £3 is legal may seem surprising, but it follows directly from the notion

that each class controls access to its own members. Pal is a friend of Base, so Pal can access the members of Base objects. That access includes access to Base objects that are embedded in an object of a type derived from Base.

When a class makes another class a friend, it is only that class to which friendship is granted. The base classes of, and classes derived from, the friend have no special access to the befriending class:

Click here to view code image

Note

Friendship is not inherited; each class controls access to its members.

Exempting Individual Members

Sometimes we need to change the access level of a name that a derived class inherits. We can do so by providing a using declaration (§3.1, p. 82):

Click here to view code image

```
class Base {
public:
    std::size_t size() const { return n; }
protected:
    std::size_t n;
};
class Derived : private Base { // note: private inheritance
public:
    // maintain access levels for members related to the size of the object
    using Base::size;
protected:
    using Base::n;
};
```

Because Derived uses private inheritance, the inherited members, size and n, are (by default) private members of Derived. The using declarations adjust the accessibility of these members. Users of Derived can access the size member, and classes subsequently derived from Derived can access n.

A using declaration inside a class can name any accessible (e.g., not private)

member of a direct or indirect base class. Access to a name specified in a using declaration depends on the access specifier preceding the using declaration. That is, if a using declaration appears in a private part of the class, that name is accessible to members and friends only. If the declaration is in a public section, the name is available to all users of the class. If the declaration is in a protected section, the name is accessible to the members, friends, and derived classes.

Note

A derived class may provide a using declaration only for names it is permitted to access.

Default Inheritance Protection Levels

In §7.2 (p. 268) we saw that classes defined with the struct and class keywords have different default access specifiers. Similarly, the default derivation specifier depends on which keyword is used to define a derived class. By default, a derived class defined with the class keyword has private inheritance; a derived class defined with struct has public inheritance:

Click here to view code image

```
class Base { /* ... */ };
struct D1 : Base { /* ... */ }; // public inheritance by default class D2 : Base { /* ... */ }; // private inheritance by default
```

It is a common misconception to think that there are deeper differences between classes defined using the struct keyword and those defined using class. The only differences are the default access specifier for members and the default derivation access specifier. There are no other distinctions.

Best Practices

A privately derived class should specify private explicitly rather than rely on the default. Being explicit makes it clear that private inheritance is intended and not an oversight.

Exercises Section 15.5

Exercise 15.18: Given the classes from page 612 and page 613, and assuming each object has the type specified in the comments, determine which of these assignments are legal. Explain why those that are illegal aren't allowed:

Click here to view code image

```
Base *p = &d1; // d1 has type Pub_Derv
p = &d2; // d2 has type Priv_Derv
p = &d3; // d3 has type Prot_Derv
p = &dd1; // dd1 has type Derived_from_Public
p = &dd2; // dd2 has type Derived_from_Private
p = &dd3; // dd3 has type Derived_from_Protected
```

Exercise 15.19: Assume that each of the classes from page 612 and page 613 has a member function of the form:

```
void memfcn(Base &b) { b = *this; }
```

For each class, determine whether this function would be legal.

Exercise 15.20: Write code to test your answers to the previous two exercises.

Exercise 15.21: Choose one of the following general abstractions containing a family of types (or choose one of your own). Organize the types into an inheritance hierarchy:

- (a) Graphical file formats (such as gif, tiff, jpeg, bmp)
- (b) Geometric primitives (such as box, circle, sphere, cone)
- (c) C++ language types (such as class, function, member function)

Exercise 15.22: For the class you chose in the previous exercise, identify some of the likely virtual functions as well as public and protected members.

15.6. Class Scope under Inheritance

Each class defines its own scope (§7.4, p. 282) within which its members are defined. Under inheritance, the scope of a derived class is nested (§2.2.4, p. 48) inside the scope of its base classes. If a name is unresolved within the scope of the derived class, the enclosing base-class scopes are searched for a definition of that name.

The fact that the scope of a derived class nests inside the scope of its base classes can be surprising. After all, the base and derived classes are defined in separate parts of our program's text. However, it is this hierarchical nesting of class scopes that allows the members of a derived class to use members of its base class as if those members were part of the derived class. For example, when we write

```
Bulk_quote bulk;
```

```
cout << bulk.isbn();</pre>
```

the use of the name isbn is resolved as follows:

- Because we called isbn on an object of type Bulk_quote, the search starts in the Bulk_quote class. The name isbn is not found in that class.
- Because Bulk_quote is derived from Disc_quote, the Disc_quote class is searched next. The name is still not found.
- Because Disc_quote is derived from Quote, the Quote class is searched next. The name isbn is found in that class; the use of isbn is resolved to the isbn in Quote.

Name Lookup Happens at Compile Time

The static type (§15.2.3, p. 601) of an object, reference, or pointer determines which members of that object are visible. Even when the static and dynamic types might differ (as can happen when a reference or pointer to a base class is used), the static type determines what members can be used. As an example, we might add a member to the Disc_quote class that returns a pair (§11.2.3, p. 426) holding the minimum (or maximum) quantity and the discounted price:

Click here to view code image

We can use discount_policy only through an object, pointer, or reference of type Disc_quote or of a class derived from Disc_quote:

Click here to view code image

```
Bulk_quote bulk;
Bulk_quote *bulkP = &bulk; // static and dynamic types are the same
Quote *itemP = &bulk; // static and dynamic types differ
bulkP->discount_policy(); // ok: bulkP has type Bulk_quote*
itemP->discount_policy(); // error: itemP has type Quote*
```

Even though bulk has a member named discount_policy, that member is not visible through itemP. The type of itemP is a pointer to Quote, which means that the search for discount_policy starts in class Quote. The Quote class has no member named discount_policy, so we cannot call that member on an object, reference, or pointer of type Quote.

Name Collisions and Inheritance

Like any other scope, a derived class can reuse a name defined in one of its direct or indirect base classes. As usual, names defined in an inner scope (e.g., a derived class) hide uses of that name in the outer scope (e.g., a base class) (§2.2.4, p. 48):

Click here to view code image

The reference to mem inside get_mem is resolved to the name inside Derived. Were we to write

Click here to view code image

```
Derived d(42);
cout << d.get_mem() << endl;  // prints 42</pre>
```

then the output would be 42.

Note

A derived-class member with the same name as a member of the base class hides direct use of the base-class member.

Using the Scope Operator to Use Hidden Members

We can use a hidden base-class member by using the scope operator:

Click here to view code image

```
struct Derived : Base {
    int get_base_mem() { return Base::mem; }
    // ...
};
```

The scope operator overrides the normal lookup and directs the compiler to look for mem starting in the scope of class Base. If we ran the code above with this version of Derived, the result of d.get_mem() would be 0.

Best Practices

Aside from overriding inherited virtual functions, a derived class usually should not reuse names defined in its base class.

Key Concept: Name Lookup and Inheritance

Understanding how function calls are resolved is crucial to understanding inheritance in C++. Given the call p->mem() (or obj.mem()), the following four steps happen:

- First determine the static type of p (or obj). Because we're calling a member, that type must be a class type.
- Look for mem in the class that corresponds to the static type of p (or obj). If mem is not found, look in the direct base class and continue up the chain of classes until mem is found or the last class is searched. If mem is not found in the class or its enclosing base classes, then the call will not compile.
- Once mem is found, do normal type checking (§6.1, p. 203) to see if this call is legal given the definition that was found.
- Assuming the call is legal, the compiler generates code, which varies depending on whether the call is virtual or not:
- If mem is virtual and the call is made through a reference or pointer, then the compiler generates code to determine at run time which version to run based on the dynamic type of the object.
- Otherwise, if the function is nonvirtual, or if the call is on an object (not a reference or pointer), the compiler generates a normal function call.

As Usual, Name Lookup Happens before Type Checking

As we've seen, functions declared in an inner scope do not overload functions declared in an outer scope (§6.4.1, p. 234). As a result, functions defined in a derived class do not overload members defined in its base class(es). As in any other scope, if a member in a derived class (i.e., in an inner scope) has the same name as a baseclass member (i.e., a name defined in an outer scope), then the derived member hides the base-class member within the scope of the derived class. The base member is hidden even if the functions have different parameter lists:

The declaration of memfcn in Derived hides the declaration of memfcn in Base. Not surprisingly, the first call through b, which is a Base object, calls the version in the base class. Similarly, the second call (through d) calls the one from Derived. What can be surprising is that the third call, d.memfcn(), is illegal.

To resolve this call, the compiler looks for the name memfcn in Derived. That class defines a member named memfcn and the search stops. Once the name is found, the compiler looks no further. The version of memfcn in Derived expects an int argument. This call provides no such argument; it is in error.

Virtual Functions and Scope

We can now understand why virtual functions must have the same parameter list in the base and derived classes (§15.3, p. 605). If the base and derived members took arguments that differed from one another, there would be no way to call the derived version through a reference or pointer to the base class. For example:

```
class Base {
public:
    virtual int fcn();
class D1 : public Base {
public:
     // hides fcn in the base; this fcn is not virtual
     // D1 inherits the definition of Base::fcn()
    int fcn(int);
                           // parameter list differs from fcn in Base
     virtual void f2(); // new virtual function that does not exist in Base
class D2 : public D1 {
public:
     int fcn(int); // nonvirtual function hides D1::fcn(int)
     int fcn(); // overrides virtual fcn from Base
    void f2();
                    // overrides virtual f2 from D1
```

```
};
```

The fcn function in D1 does not override the virtual fcn from Base because they have different parameter lists. Instead, it hides fcn from the base. Effectively, D1 has two functions named fcn: D1 inherits a virtual named fcn from Base and defines its own, nonvirtual member named fcn that takes an int parameter.

Calling a Hidden Virtual through the Base Class

Given the classes above, let's look at several different ways to call these functions:

Click here to view code image

```
Base bobj; D1 dlobj; D2 d2obj;
Base *bp1 = &bobj, *bp2 = &dlobj, *bp3 = &d2obj;
bp1->fcn(); // virtual call, will call Base::fcn at run time
bp2->fcn(); // virtual call, will call Base::fcn at run time
bp3->fcn(); // virtual call, will call D2::fcn at run time
D1 *dlp = &dlobj; D2 *d2p = &d2obj;
bp2->f2(); // error: Base has no member named f2
dlp->f2(); // virtual call, will call D1::f2() at run time
d2p->f2(); // virtual call, will call D2::f2() at run time
```

The first three calls are all made through pointers to the base class. Because fcn is virtual, the compiler generates code to decide at run time which version to call. That decision will be based on the actual type of the object to which the pointer is bound. In the case of bp2, the underlying object is a D1. That class did not override the fcn function that takes no arguments. Thus, the call through bp2 is resolved (at run time) to the version defined in Base.

The next three calls are made through pointers with differing types. Each pointer points to one of the types in this hierarchy. The first call is illegal because there is no f2() in class Base. The fact that the pointer happens to point to a derived object is irrelevant.

For completeness, let's look at calls to the nonvirtual function fcn(int):

Click here to view code image

```
Base *p1 = &d2obj; D1 *p2 = &d2obj; D2 *p3 = &d2obj; p1->fcn(42); // error: Base has no version of fcn that takes an int p2->fcn(42); // statically bound, calls D1::fcn(int) p3->fcn(42); // statically bound, calls D2::fcn(int)
```

In each call the pointer happens to point to an object of type D2. However, the dynamic type doesn't matter when we call a nonvirtual function. The version that is called depends only on the static type of the pointer.

Overriding Overloaded Functions

As with any other function, a member function (virtual or otherwise) can be overloaded. A derived class can override zero or more instances of the overloaded functions it inherits. If a derived class wants to make all the overloaded versions available through its type, then it must override all of them or none of them.

Sometimes a class needs to override some, but not all, of the functions in an overloaded set. It would be tedious in such cases to have to override every base-class version in order to override the ones that the class needs to specialize.

Instead of overriding every base-class version that it inherits, a derived class can provide a using declaration (§15.5, p. 615) for the overloaded member. A using declaration specifies only a name; it may not specify a parameter list. Thus, a using declaration for a base-class member function adds all the overloaded instances of that function to the scope of the derived class. Having brought all the names into its scope, the derived class needs to define only those functions that truly depend on its type. It can use the inherited definitions for the others.

The normal rules for a using declaration inside a class apply to names of overloaded functions (§15.5, p. 615); every overloaded instance of the function in the base class must be accessible to the derived class. The access to the overloaded versions that are not otherwise redefined by the derived class will be the access in effect at the point of the using declaration.

Exercises Section 15.6

Exercise 15.23: Assuming class D1 on page 620 had intended to override its inherited fcn function, how would you fix that class? Assuming you fixed the class so that fcn matched the definition in Base, how would the calls in that section be resolved?

15.7. Constructors and Copy Control

Like any other class, a class in an inheritance hierarchy controls what happens when objects of its type are created, copied, moved, assigned, or destroyed. As for any other class, if a class (base or derived) does not itself define one of the copy-control operations, the compiler will synthesize that operation. Also, as usual, the synthesized version of any of these members might be a deleted function.

15.7.1. Virtual Destructors

The primary direct impact that inheritance has on copy control for a base class is that a base class generally should define a virtual destructor (§15.2.1, p. 594). The

destructor needs to be virtual to allow objects in the inheritance hierarchy to be dynamically allocated.

Recall that the destructor is run when we delete a pointer to a dynamically allocated object (§13.1.3, p. 502). If that pointer points to a type in an inheritance hierarchy, it is possible that the static type of the pointer might differ from the dynamic type of the object being destroyed (§15.2.2, p. 597). For example, if we delete a pointer of type Quote*, that pointer might point at a Bulk_quote object. If the pointer points at a Bulk_quote, the compiler has to know that it should run the Bulk_quote destructor. As with any other function, we arrange to run the proper destructor by defining the destructor as virtual in the base class:

Click here to view code image

```
class Quote {
public:
    // virtual destructor needed if a base pointer pointing to a derived object is deleted
    virtual ~Quote() = default; // dynamic binding for the destructor
};
```

Like any other virtual, the virtual nature of the destructor is inherited. Thus, classes derived from Quote have virtual destructors, whether they use the synthesized destructor or define their own version. So long as the base class destructor is virtual, when we delete a pointer to base, the correct destructor will be run:

Click here to view code image

```
Quote *itemP = new Quote; // same static and dynamic type
delete itemP; // destructor for Quote called
itemP = new Bulk_quote; // static and dynamic types differ
delete itemP; // destructor for Bulk_quote called
```

Executing delete on a pointer to base that points to a derived object has undefined behavior if the base's destructor is not virtual.

Destructors for base classes are an important exception to the rule of thumb that if a class needs a destructor, it also needs copy and assignment (§13.1.4, p. 504). A base class almost always needs a destructor, so that it can make the destructor virtual. If a base class has an empty destructor in order to make it virtual, then the fact that the class has a destructor does not indicate that the assignment operator or copy constructor is also needed.

Virtual Destructors Turn Off Synthesized Move

The fact that a base class needs a virtual destructor has an important indirect impact on the definition of base and derived classes: If a class defines a destructor—even if it uses = default to use the synthesized version—the compiler will not synthesize a move operation for that class (§13.6.2, p. 537).

Exercises Section 15.7.1

Exercise 15.24: What kinds of classes need a virtual destructor? What operations must a virtual destructor perform?

15.7.2. Synthesized Copy Control and Inheritance

The synthesized copy-control members in a base or a derived class execute like any other synthesized constructor, assignment operator, or destructor: They memberwise initialize, assign, or destroy the members of the class itself. In addition, these synthesized members initialize, assign, or destroy the direct base part of an object by using the corresponding operation from the base class. For example,

- The synthesized Bulk_quote default constructor runs the Disc_Quote default constructor, which in turn runs the Quote default constructor.
- The Quote default constructor default initializes the bookNo member to the empty string and uses the in-class initializer to initialize price to zero.
- When the Quote constructor finishes, the Disc_Quote constructor continues, which uses the in-class initializers to initialize qty and discount.
- When the Disc_quote constructor finishes, the Bulk_quote constructor continues but has no other work to do.

Similarly, the synthesized Bulk_quote copy constructor uses the (synthesized) Disc_quote copy constructor, which uses the (synthesized) Quote copy constructor. The Quote copy constructor copies the bookNo and price members; and the Disc_Quote copy constructor copies the qty and discount members.

It is worth noting that it doesn't matter whether the base-class member is itself synthesized (as is the case in our Quote hierarchy) or has a an user-provided definition. All that matters is that the corresponding member is accessible (§15.5, p. 611) and that it is not a deleted function.

Each of our Quote classes use the synthesized destructor. The derived classes do so implicitly, whereas the Quote class does so explicitly by defining its (virtual) destructor as = default. The synthesized destructor is (as usual) empty and its implicit destruction part destroys the members of the class (§13.1.3, p. 501). In addition to destroying its own members, the destruction phase of a destructor in a derived class also destroys its direct base. That destructor in turn invokes the

destructor for its own direct base, if any. And, so on up to the root of the hierarchy.

As we've seen, Quote does not have synthesized move operations because it defines a destructor. The (synthesized) copy operations will be used whenever we move a Quote object (§13.6.2, p. 540). As we're about to see, the fact that Quote does not have move operations means that its derived classes don't either.

Base Classes and Deleted Copy Control in the Derived

The synthesized default constructor, or any of the copy-control members of either a base or a derived class, may be defined as deleted for the same reasons as in any other class (§13.1.6, p. 508, and §13.6.2, p. 537). In addition, the way in which a base class is defined can cause a derived-class member to be defined as deleted:

- If the default constructor, copy constructor, copy-assignment operator, or destructor in the base class is deleted or inaccessible (§15.5, p. 612), then the corresponding member in the derived class is defined as deleted, because the compiler can't use the base-class member to construct, assign, or destroy the base-class part of the object.
- If the base class has an inaccessible or deleted destructor, then the synthesized default and copy constructors in the derived classes are defined as deleted, because there is no way to destroy the base part of the derived object.
- As usual, the compiler will not synthesize a deleted move operation. If we use = default to request a move operation, it will be a deleted function in the derived if the corresponding operation in the base is deleted or inaccessible, because the base class part cannot be moved. The move constructor will also be deleted if the base class destructor is deleted or inaccessible.

As an example, this base class, B,

Click here to view code image

```
class B {
public:
    B();
    B(const B&) = delete;
    // other members, not including a move constructor
};
class D : public B {
    // no constructors
};
D d; // ok: D's synthesized default constructor uses B's default constructor
D d2(d); // error: D's synthesized copy constructor is deleted
D d3(std::move(d)); // error: implicitly uses D's deleted copy constructor
```

has an accessible default constructor and an explicitly deleted copy constructor. Because the copy constructor is defined, the compiler will not synthesize a move

constructor for class B (§13.6.2, p. 537). As a result, we can neither move nor copy objects of type B. If a class derived from B wanted to allow its objects to be copied or moved, that derived class would have to define its own versions of these constructors. Of course, that class would have to decide how to copy or move the members in it base-class part. In practice, if a base class does not have a default, copy, or move constructor, then its derived classes usually don't either.

Move Operations and Inheritance

As we've seen, most base classes define a virtual destructor. As a result, by default, base classes generally do not get synthesized move operations. Moreover, by default, classes derived from a base class that doesn't have move operations don't get synthesized move operations either.

Because lack of a move operation in a base class suppresses synthesized move for its derived classes, base classes ordinarily should define the move operations if it is sensible to do so. Our Quote class can use the synthesized versions. However, Quote must define these members explicitly. Once it defines its move operations, it must also explicitly define the copy versions as well (§13.6.2, p. 539):

Click here to view code image

Now, Quote objects will be memberwise copied, moved, assigned, and destroyed. Moreover, classes derived from Quote will automatically obtain synthesized move operations as well, unless they have members that otherwise preclude move.

Exercises Section 15.7.2

Exercise 15.25: Why did we define a default constructor for Disc_quote? What effect, if any, would removing that constructor have on the behavior of Bulk quote?

15.7.3. Derived-Class Copy-Control Members

As we saw in §15.2.2 (p. 598), the initialization phase of a derived-class constructor initializes the base-class part(s) of a derived object as well as initializing its own members. As a result, the copy and move constructors for a derived class must copy/move the members of its base part as well as the members in the derived. Similarly, a derived-class assignment operator must assign the members in the base part of the derived object.

Unlike the constructors and assignment operators, the destructor is responsible only for destroying the resources allocated by the derived class. Recall that the members of an object are implicitly destroyed (§13.1.3, p. 502). Similarly, the base-class part of a derived object is destroyed automatically.

Warning

When a derived class defines a copy or move operation, that operation is responsible for copying or moving the entire object, including base-class members.

Defining a Derived Copy or Move Constructor

When we define a copy or move constructor (§13.1.1, p. 496, and §13.6.2, p. 534) for a derived class, we ordinarily use the corresponding base-class constructor to initialize the base part of the object:

Click here to view code image

```
class Base { /* ... */ };
class D: public Base {
public:
     // by default, the base class default constructor initializes the base part of an object
     // to use the copy or move constructor, we must explicitly call that
     // constructor in the constructor initializer list
     D(const D& d): Base(d)
                                          // copy the base members
                      /* initializers for members of D */ \{ /* ...
                                                                       */ }
     D(D&& d): Base(std::move(d)) // move the base members
                      /* initializers for members of D */ \{ /* ...
                                                                       */ }
};
```

The initializer Base(d) passes a D object to a base-class constructor. Although in principle, Base could have a constructor that has a parameter of type D, in practice, that is very unlikely. Instead, Base (d) will (ordinarily) match the Base copy constructor. The D object, d, will be bound to the Base& parameter in that

constructor. The Base copy constructor will copy the base part of d into the object that is being created. Had the initializer for the base class been omitted,

Click here to view code image

the Base default constructor would be used to initialize the base part of a \D object. Assuming \D 's constructor copies the derived members from \D , this newly constructed object would be oddly configured: Its Base members would hold default values, while its \D members would be copies of the data from another object.

By default, the base-class default constructor initializes the base-class part of a derived object. If we want copy (or move) the base-class part, we must explicitly use the copy (or move) constructor for the base class in the derived's constructor initializer list.

Derived-Class Assignment Operator

Like the copy and move constructors, a derived-class assignment operator (§13.1.2, p. 500, and §13.6.2, p. 536), must assign its base part explicitly:

Click here to view code image

```
// Base::operator=(const Base&) is not invoked automatically
D &D::operator=(const D &rhs)
{
    Base::operator=(rhs); // assigns the base part
    // assign the members in the derived class, as usual,
    // handling self-assignment and freeing existing resources as appropriate
    return *this;
}
```

This operator starts by explicitly calling the base-class assignment operator to assign the members of the base part of the derived object. The base-class operator will (presumably) correctly handle self-assignment and, if appropriate, will free the old value in the base part of the left-hand operand and assign the new values from rhs. Once that operator finishes, we continue doing whatever is needed to assign the members in the derived class.

It is worth noting that a derived constructor or assignment operator can use its corresponding base class operation regardless of whether the base defined its own

version of that operator or uses the synthesized version. For example, the call to Base: :operator= executes the copy-assignment operator in class Base. It is immaterial whether that operator is defined explicitly by the Base class or is synthesized by the compiler.

Derived-Class Destructor

Recall that the data members of an object are implicitly destroyed after the destructor body completes (§13.1.3, p. 502). Similarly, the base-class parts of an object are also implicitly destroyed. As a result, unlike the constructors and assignment operators, a derived destructor is responsible only for destroying the resources allocated by the derived class:

Click here to view code image

```
class D: public Base {
public:
    // Base::~Base invoked automatically
    ~D() { /* do what it takes to clean up derived members */ }
};
```

Objects are destroyed in the opposite order from which they are constructed: The derived destructor is run first, and then the base-class destructors are invoked, back up through the inheritance hierarchy.

Calls to Virtuals in Constructors and Destructors

As we've seen, the base-class part of a derived object is constructed first. While the base-class constructor is executing, the derived part of the object is uninitialized. Similarly, derived objects are destroyed in reverse order, so that when a base class destructor runs, the derived part has already been destroyed. As a result, while these base-class members are executing, the object is incomplete.

To accommodate this incompleteness, the compiler treats the object as if its type changes during construction or destruction. That is, while an object is being constructed it is treated as if it has the same class as the constructor; calls to virtual functions will be bound as if the object has the same type as the constructor itself. Similarly, for destructors. This binding applies to virtuals called directly or that are called indirectly from a function that the constructor (or destructor) calls.

To understand this behavior, consider what would happen if the derived-class version of a virtual was called from a base-class constructor. This virtual probably accesses members of the derived object. After all, if the virtual didn't need to use members of the derived object, the derived class probably could use the version in its base class. However, those members are uninitialized while a base constructor is running. If such access were allowed, the program would probably crash.

Note

If a constructor or destructor calls a virtual, the version that is run is the one corresponding to the type of the constructor or destructor itself.

Exercises Section 15.7.3

Exercise 15.26: Define the Quote and Bulk_quote copy-control members to do the same job as the synthesized versions. Give them and the other constructors print statements that identify which function is running. Write programs using these classes and predict what objects will be created and destroyed. Compare your predictions with the output and continue experimenting until your predictions are reliably correct.

15.7.4. Inherited Constructors

Under the new standard, a derived class can reuse the constructors defined by its direct base class. Although, as we'll see, such constructors are not inherited in the normal sense of that term, it is nonetheless common to refer to such constructors as "inherited." For the same reasons that a class may initialize only its direct base class, a class may inherit constructors only from its direct base. A class cannot inherit the default, copy, and move constructors. If the derived class does not directly define these constructors, the compiler synthesizes them as usual.

A derived class inherits its base-class constructors by providing a using declaration that names its (direct) base class. As an example, we can redefine our Bulk_quote class (§15.4, p. 610) to inherit its constructors from Disc quote:

Click here to view code image

```
class Bulk_quote : public Disc_quote {
public:
    using Disc_quote::Disc_quote; // inherit Disc_quote's constructors
    double net_price(std::size_t) const;
};
```

Ordinarily, a using declaration only makes a name visible in the current scope. When applied to a constructor, a using declaration causes the compiler to generate code. The compiler generates a derived constructor corresponding to each constructor in the base. That is, for each constructor in the base class, the compiler generates a constructor in the derived class that has the same parameter list.

These compiler-generated constructors have the form

derived(parms) : base(args) { }

where *derived* is the name of the derived class, *base* is the name of the base class, *parms* is the parameter list of the constructor, and *args* pass the parameters from the derived constructor to the base constructor. In our Bulk_quote class, the inherited constructor would be equivalent to

Click here to view code image

If the derived class has any data members of its own, those members are default initialized (§7.1.4, p. 266).

Characteristics of an Inherited Constructor

Unlike using declarations for ordinary members, a constructor using declaration does not change the access level of the inherited constructor(s). For example, regardless of where the using declaration appears, a private constructor in the base is a private constructor in the derived; similarly for protected and public constructors.

Moreover, a using declaration can't specify explicit or constexpr. If a constructor in the base is explicit (§7.5.4, p. 296) or constexpr (§7.5.6, p. 299), the inherited constructor has the same property.

If a base-class constructor has default arguments (§6.5.1, p. 236), those arguments are not inherited. Instead, the derived class gets multiple inherited constructors in which each parameter with a default argument is successively omitted. For example, if the base has a constructor with two parameters, the second of which has a default, the derived class will obtain two constructors: one with both parameters (and no default argument) and a second constructor with a single parameter corresponding to the left-most, non-defaulted parameter in the base class.

If a base class has several constructors, then with two exceptions, the derived class inherits each of the constructors from its base class. The first exception is that a derived class can inherit some constructors and define its own versions of other constructors. If the derived class defines a constructor with the same parameters as a constructor in the base, then that constructor is not inherited. The one defined in the derived class is used in place of the inherited constructor.

The second exception is that the default, copy, and move constructors are not inherited. These constructors are synthesized using the normal rules. An inherited constructor is not treated as a user-defined constructor. Therefore, a class that contains only inherited constructors will have a synthesized default constructor.

Exercise 15.27: Redefine your Bulk quote class to inherit its constructors.

15.8. Containers and Inheritance

When we use a container to store objects from an inheritance hierarchy, we generally must store those objects indirectly. We cannot put objects of types related by inheritance directly into a container, because there is no way to define a container that holds elements of differing types.

As an example, assume we want to define a vector to hold several books that a customer wants to buy. It should be easy to see that we can't use a vector that holds Bulk_quote objects. We can't convert Quote objects to Bulk_quote (§15.2.3, p. 602), so we wouldn't be able to put Quote objects into that vector.

It may be somewhat less obvious that we also can't use a vector that holds objects of type Quote. In this case, we can put Bulk_quote objects into the container. However, those objects would no longer be Bulk_quote objects:

Click here to view code image

```
vector<Ouote> basket;
basket.push_back(Quote("0-201-82470-1", 50));
// ok, but copies only the Quote part of the object into basket
basket.push_back(Bulk_quote("0-201-54848-8", 50, 10, .25));
// calls version defined by Quote, prints 750, i.e., 15 * $50
cout << basket.back().net_price(15) << endl;</pre>
```

The elements in basket are Quote objects. When we add a Bulk_quote object to the vector its derived part is ignored (§15.2.3, p. 603).

Warning

Because derived objects are "sliced down" when assigned to a base-type object, containers and types related by inheritance do not mix well.

Put (Smart) Pointers, Not Objects, in Containers

When we need a container that holds objects related by inheritance, we typically define the container to hold pointers (preferably smart pointers (§12.1, p. 450)) to the base class. As usual, the dynamic type of the object to which those pointers point might be the base-class type or a type derived from that base:

Click here to view code image

```
vector<shared_ptr<Quote>> basket;
basket.push_back(make_shared<Quote>("0-201-82470-1", 50));
basket.push_back(
          make_shared<Bulk_quote>("0-201-54848-8", 50, 10, .25));
// calls the version defined by Quote; prints 562.5, i.e., 15 * $50 less the discount
cout << basket.back()->net_price(15) << endl;</pre>
```

Because basket holds shared_ptrs, we must dereference the value returned by basket.back() to get the object on which to run net_price. We do so by using - > in the call to net_price. As usual, the version of net_price that is called depends on the dynamic type of the object to which that pointer points.

It is worth noting that we defined basket as shared_ptr<Quote>, yet in the second push_back we passed a shared_ptr to a Bulk_quote object. Just as we can convert an ordinary pointer to a derived type to a pointer to an base-class type (§15.2.2, p. 597), we can also convert a smart pointer to a derived type to a smart pointer to an base-class type. Thus, make_shared<Bulk_quote> returns a shared_ptr<Bulk_quote> object, which is converted to shared_ptr<Quote> when we call push_back. As a result, despite appearances, all of the elements of basket have the same type.

Exercises Section 15.8

Exercise 15.28: Define a vector to hold Quote objects but put Bulk_quote objects into that vector. Compute the total net_price of all the elements in the vector.

Exercise 15.29: Repeat your program, but this time store <code>shared_ptrs</code> to objects of type <code>Quote</code>. Explain any discrepancy in the sum generated by the this version and the previous program. If there is no discrepancy, explain why there isn't one.

15.8.1. Writing a Basket Class

One of the ironies of object-oriented programming in C++ is that we cannot use objects directly to support it. Instead, we must use pointers and references. Because pointers impose complexity on our programs, we often define auxiliary classes to help manage that complexity. We'll start by defining a class to represent a basket:

```
class Basket {
public:
    // Basket uses synthesized default constructor and copy-control members
```

Our class uses a multiset (§11.2.1, p. 423) to hold the transactions, so that we can store multiple transactions for the same book, and so that all the transactions for a given book will be kept together (§11.2.2, p. 424).

The elements in our multiset are shared_ptrs and there is no less-than operator for shared_ptr. As a result, we must provide our own comparison operation to order the elements (§11.2.2, p. 425). Here, we define a private static member, named compare, that compares the isbns of the objects to which the shared_ptrs point. We initialize our multiset to use this comparison function through an in-class initializer (§7.3.1, p. 274):

Click here to view code image

This declaration can be hard to read, but reading from left to right, we see that we are defining a multiset of shared_ptrs to Quote objects. The multiset will use a function with the same type as our compare member to order the elements. The multiset member is named items, and we're initializing items to use our compare function.

Defining the Members of Basket

The Basket class defines only two operations. We defined the add_item member inside the class. That member takes a shared_ptr to a dynamically allocated Quote and puts that shared_ptr into the multiset. The second member, total_receipt, prints an itemized bill for the contents of the basket and returns the price for all the items in the basket:

```
double Basket::total_receipt(ostream &os) const
{
```

Our for loop starts by defining and initializing iter to refer to the first element in the multiset. The condition checks whether iter is equal to items.cend(). If so, we've processed all the purchases and we drop out of the for. Otherwise, we process the next book.

The interesting bit is the "increment" expression in the for. Rather than the usual loop that reads each element, we advance iter to refer to the next key. We skip over all the elements that match the current key by calling upper_bound (§11.3.5, p. 438). The call to upper_bound returns the iterator that refers to the element just past the last one with the same key as in iter. The iterator we get back denotes either the end of the set or the next book.

Inside the for loop, we call print_total (§15.1, p. 593) to print the details for each book in the basket:

Click here to view code image

```
sum += print_total(os, **iter, items.count(*iter));
```

The arguments to print_total are an ostream on which to write, a Quote object to process, and a count. When we dereference iter, we get a shared_ptr that points to the object we want to print. To get that object, we must dereference that shared_ptr. Thus, **iter is a Quote object (or an object of a type derived from Quote). We use the multiset count member (§11.3.5, p. 436) to determine how many elements in the multiset have the same key (i.e., the same ISBN).

As we've seen, print_total makes a virtual call to net_price, so the resulting price depends on the dynamic type of **iter. The print_total function prints the total for the given book and returns the total price that it calculated. We add that result into sum, which we print after we complete the for loop.

Hiding the Pointers

Users of Basket still have to deal with dynamic memory, because add_item takes a

shared_ptr. As a result, users have to write code such as

Click here to view code image

```
Basket bsk;
bsk.add_item(make_shared<Quote>("123", 45));
bsk.add_item(make_shared<Bulk_quote>("345", 45, 3, .15));
```

Our next step will be to redefine add_item so that it takes a Quote object instead of a shared_ptr. This new version of add_item will handle the memory allocation so that our users no longer need to do so. We'll define two versions, one that will copy its given object and the other that will move from it (§13.6.3, p. 544):

Click here to view code image

```
void add_item(const Quote& sale); // copy the given object
void add_item(Quote&& sale); // move the given object
```

The only problem is that add_item doesn't know what type to allocate. When it does its memory allocation, add_item will copy (or move) its sale parameter. Somewhere there will be a new expression such as:

```
new Quote(sale)
```

Unfortunately, this expression won't do the right thing: new allocates an object of the type we request. This expression allocates an object of type Quote and copies the Quote portion of sale. However, sale might refer to a Bulk_quote object, in which case, that object will be sliced down.

Simulating Virtual Copy

We'll solve this problem by giving our Quote classes a virtual member that allocates a copy of itself.

```
class Ouote {
public:
     // virtual function to return a dynamically allocated copy of itself
     // these members use reference qualifiers; see §13.6.3 (p. 546)
            virtual Ouote* clone() const
                                                         {return
                                                                    new
Quote(*this);}
  virtual Quote* clone() &&
                                                         {return
                                                                    new
Quote(std::move(*this));}
    // other members as before
};
class Bulk_quote : public Quote {
              Bulk_quote*
                              clone()
                                                         {return
                                          const
                                                                    new
Bulk_quote(*this);}
```

```
Bulk_quote* clone() &&

Bulk_quote(std::move(*this));

// other members as before
};
```

Because we have a copy and a move version of add_item, we defined Ivalue and rvalue versions of clone (§13.6.3, p. 546). Each clone function allocates a new object of its own type. The const Ivalue reference member copies itself into that newly allocated object; the rvalue reference member moves its own data.

Using clone, it is easy to write our new versions of add_item:

Click here to view code image

Like add_item itself, clone is overloaded based on whether it is called on an Ivalue or an rvalue. Thus, the first version of add_item calls the const Ivalue version of clone, and the second version calls the rvalue reference version. Note that in the rvalue version, although the type of sale is an rvalue reference type, sale (like any other variable) is an Ivalue (§13.6.1, p. 533). Therefore, we call move to bind an rvalue reference to sale.

Our clone function is also virtual. Whether the Quote or Bulk_quote function is run, depends (as usual) on the dynamic type of sale. Regardless of whether we copy or move the data, clone returns a pointer to a newly allocated object, of its own type. We bind a shared_ptr to that object and call insert to add this newly allocated object to items. Note that because shared_ptr supports the derived-to-base conversion (§15.2.2, p. 597), we can bind a shared_ptr<Quote to a Bulk quote*.

Exercises Section 15.8.1

Exercise 15.30: Write your own version of the Basket class and use it to compute prices for the same transactions as you used in the previous exercises.

15.9. Text Queries Revisited

As a final example of inheritance, we'll extend our text-query application from §12.3 (p. 484). The classes we wrote in that section let us look for occurrences of a given word in a file. We'd like to extend the system to support more complicated queries. In our examples, we'll run queries against the following simple story:

Alice Emma has long flowing red hair.
Her Daddy says when the wind blows
through her hair, it looks almost alive,
like a fiery bird in flight.
A beautiful fiery bird, he tells her,
magical but untamed.
"Daddy, shush, there is no such thing,"
she tells him, at the same time wanting
him to tell her more.
Shyly, she asks, "I mean, Daddy, is there?"

Our system should support the following queries:

• Word queries find all the lines that match a given string:

Executing Query for:

Daddy Daddy occurs 3 times

(line 2) Her Daddy says when the wind blows

(line 7) "Daddy, shush, there is no such thing,"

(line 10) Shyly, she asks, "I mean, Daddy, is there?"

• Not queries, using the ~ operator, yield lines that don't match the query:

Executing Query for: ~(Alice)

~(Alice) occurs 9 times

(line 2) Her Daddy says when the wind blows

(line 3) through her hair, it looks almost alive,

(line 4) like a fiery bird in flight.

. . .

• Or queries, using the | operator, return lines matching either of two queries:

Executing Query for: (hair | Alice)

(hair | Alice) occurs 2 times

(line 1) Alice Emma has long flowing red hair.

(line 3) through her hair, it looks almost alive,

• And queries, using the & operator, return lines matching both queries:

Executing query for: (hair & Alice)

(hair & Alice) occurs 1 time

(line 1) Alice Emma has long flowing red hair.

Moreover, we want to be able to combine these operations, as in

fiery & bird | wind

We'll use normal C++ precedence rules (§4.1.2, p. 136) to evaluate compound expressions such as this example. Thus, this query will match a line in which both fiery and bird appear or one in which wind appears:

```
Executing Query for: ((fiery & bird) | wind) ((fiery & bird) | wind) occurs 3 times (line 2) Her Daddy says when the wind blows (line 4) like a fiery bird in flight. (line 5) A beautiful fiery bird, he tells her,
```

Our output will print the query, using parentheses to indicate the way in which the query was interpreted. As with our original implementation, our system will display lines in ascending order and will not display the same line more than once.

15.9.1. An Object-Oriented Solution

We might think that we should use the TextQuery class from §12.3.2 (p. 487) to represent our word query and derive our other queries from that class.

However, this design would be flawed. To see why, consider a Not query. A Word query looks for a particular word. In order for a Not query to be a kind of Word query, we would have to be able to identify the word for which the Not query was searching. In general, there is no such word. Instead, a Not query has a query (a Word query or any other kind of query) whose value it negates. Similarly, an And query and an Or query have two queries whose results it combines.

This observation suggests that we model our different kinds of queries as independent classes that share a common base class:

```
WordQuery // Daddy
NotQuery // ~Alice
OrQuery // hair | Alice
AndQuery // hair & Alice
```

These classes will have only two operations:

- eval, which takes a TextQuery object and returns a QueryResult. The eval function will use the given TextQuery object to find the query's the matching lines.
- rep, which returns the string representation of the underlying query. This function will be used by eval to create a QueryResult representing the match and by the output operator to print the query expressions.

Abstract Base Class

As we've seen, our four query types are not related to one another by inheritance; they are conceptually siblings. Each class shares the same interface, which suggests that we'll need to define an abstract base class (§15.4, p. 610) to represent that interface. We'll name our abstract base class Query_base, indicating that its role is to serve as the root of our query hierarchy.

Our Query_base class will define eval and rep as pure virtual functions (§15.4, p. 610). Each of our classes that represents a particular kind of query must override these functions. We'll derive WordQuery and NotQuery directly from Query_base. The AndQuery and OrQuery classes share one property that the other classes in our system do not: Each has two operands. To model this property, we'll define another abstract base class, named BinaryQuery, to represent queries with two operands. The AndQuery and OrQuery classes will inherit from BinaryQuery, which in turn will inherit from Query_base. These decisions give us the class design represented in Figure 15.2.

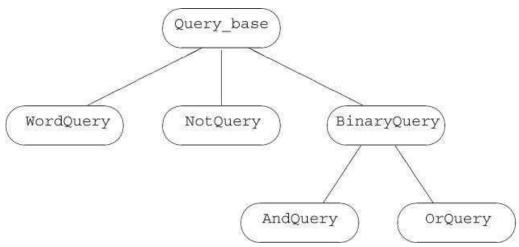

Figure 15.2. Query_base Inheritance Hierarchy

Key Concept: Inheritance versus Composition

The design of inheritance hierarchies is a complicated topic in its own right and well beyond the scope of this language Primer. However, there is one important design guide that is so fundamental that every programmer should be familiar with it.

When we define a class as publicly inherited from another, the derived class should reflect an "Is A" relationship to the base class. In well-designed class hierarchies, objects of a publicly derived class can be used wherever an object of the base class is expected.

Another common relationship among types is a "Has A" relationship. Types related by a "Has A" relationship imply membership.

In our bookstore example, our base class represents the concept of a quote for a book sold at a stipulated price. Our Bulk_quote "is a" kind of

quote, but one with a different pricing strategy. Our bookstore classes "have a" price and an ISBN.

Hiding a Hierarchy in an Interface Class

Our program will deal with evaluating queries, not with building them. However, we need to be able to create queries in order to run our program. The simplest way to do so is to write C++ expressions to create the queries. For example, we'd like to generate the compound query previously described by writing code such as

Click here to view code image

```
Query q = Query("fiery") & Query("bird") | Query("wind");
```

This problem description implicitly suggests that user-level code won't use the inherited classes directly. Instead, we'll define an interface class named <code>Query</code>, which will hide the hierarchy. The <code>Query</code> class will store a pointer to <code>Query_base</code>. That pointer will be bound to an object of a type derived from <code>Query_base</code>. The <code>Query</code> class will provide the same operations as the <code>Query_base</code> classes: <code>eval</code> to evaluate the associated query, and <code>rep</code> to generate a <code>string</code> version of the query. It will also define an overloaded output operator to display the associated query.

Users will create and manipulate Query_base objects only indirectly through operations on Query objects. We'll define three overloaded operators on Query objects, along with a Query constructor that takes a string. Each of these functions will dynamically allocate a new object of a type derived from Query_base:

- The & operator will generate a Query bound to a new AndQuery.
- The | operator will generate a Query bound to a new OrQuery.
- The ~ operator will generate a Query bound to a new NotQuery.
- The Query constructor that takes a string will generate a new WordQuery.

Understanding How These Classes Work

It is important to realize that much of the work in this application consists of building objects to represent the user's query. For example, an expression such as the one above generates the collection of interrelated objects illustrated in Figure 15.3.

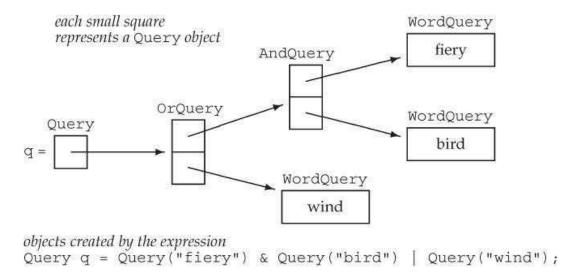

Figure 15.3. Objects Created by Query Expressions

Once the tree of objects is built up, evaluating (or generating the representation of) a query is basically a process (managed for us by the compiler) of following these links, asking each object to evaluate (or display) itself. For example, if we call eval on q (i.e., on the root of the tree), that call asks the OrQuery to which q points to eval itself. Evaluating this OrQuery calls eval on its two operands—on the AndQuery and the WordQuery that looks for the word wind. Evaluating the AndQuery evaluates its two WordQuerys, generating the results for the words fiery and bird, respectively.

When new to object-oriented programming, it is often the case that the hardest part in understanding a program is understanding the design. Once you are thoroughly comfortable with the design, the implementation flows naturally. As an aid to understanding this design, we've summarized the classes used in this example in Table 15.1 (overleaf).

Table 15.1. Recap: Query Program Design

	Query Program Interface Classes and Operations
TextQuery	Class that reads a given file and builds a lookup map. This class has a query operation that takes a string argument and returns a QueryResult representing the lines on which that string appears (§ 12.3.2, p. 487).
QueryResult	Class that holds the results of a query operation (§ 12.3.2, p. 489).
Query	Interface class that points to an object of a type derived from Query_base.
Queryq(s)	Binds the Query q to a new WordQuery holding the string s.
q1 & q2	Returns a Query bound to a new AndQuery object holding q1 and q2.
q1 q2	Returns a Query bound to a new OrQuery object holding q1 and q2.
~q	Returns a Query bound to a new NotQuery object holding q.
	Query Program Implementation Classes
Query_base	Abstract base class for the query classes.
WordQuery	Class derived from Query_base that looks for a given word.
NotQuery	Class derived from Query_base that represents the set of lines in which its Query operand does not appear.
BinaryQuery	Abstract base class derived from Query_base that represents queries with two Query operands.
OrQuery	Class derived from BinaryQuery that returns the union of the line numbers in which its two operands appear.
AndQuery	Class derived from BinaryQuery that returns the intersection of the line numbers in which its two operands appear.

Exercises Section 15.9.1

Exercise 15.31: Given that s1, s2, s3, and s4 are all strings, determine what objects are created in the following expressions:

Click here to view code image

```
(a) Query(s1) | Query(s2) & ~ Query(s3);
(b) Query(s1) | (Query(s2) & ~ Query(s3));
(c) (Query(s1) & (Query(s2)) | (Query(s3) & Query(s4)));
```

15.9.2. The Query_base and Query Classes

We'll start our implementation by defining the Query_base class:

```
// abstract class acts as a base class for concrete query types; all members are private
class Query_base {
    friend class Query;
protected:
```

```
using line_no = TextQuery::line_no; // used in the eval
functions
    virtual ~Query_base() = default;
private:
    // eval returns the QueryResult that matches this Query
    virtual QueryResult eval(const TextQuery&) const = 0;
    // rep is a string representation of the query
    virtual std::string rep() const = 0;
};
```

Both eval and rep are pure virtual functions, which makes Query_base an abstract base class (§15.4, p. 610). Because we don't intend users, or the derived classes, to use Query_base directly, Query_base has no public members. All use of Query_base will be through Query objects. We grant friendship to the Query class, because members of Query will call the virtuals in Query_base.

The protected member, line_no, will be used inside the eval functions. Similarly, the destructor is protected because it is used (implicitly) by the destructors in the derived classes.

The Query Class

The Query class provides the interface to (and hides) the Query_base inheritance hierarchy. Each Query object will hold a shared_ptr to a corresponding Query_base object. Because Query is the only interface to the Query_base classes, Query must define its own versions of eval and rep.

The Query constructor that takes a string will create a new WordQuery and bind its shared_ptr member to that newly created object. The &, |, and ~ operators will create AndQuery, OrQuery, and NotQuery objects, respectively. These operators will return a Query object bound to its newly generated object. To support these operators, Query needs a constructor that takes a shared_ptr to a Query_base and stores its given pointer. We'll make this constructor private because we don't intend general user code to define Query_base objects. Because this constructor is private, we'll need to make the operators friends.

Given the preceding design, the Query class itself is simple:

```
// interface class to manage the Query_base inheritance hierarchy
class Query {
    // these operators need access to the shared_ptr constructor
    friend Query operator~(const Query &);
    friend Query operator|(const Query&, const Query&);
    friend Query operator&(const Query&, const Query&);
    public:
        Query(const std::string&); // builds a new WordQuery
        // interface functions: call the corresponding Query_base operations
```

We start by naming as friends the operators that create Query objects. These operators need to be friends in order to use the private constructor.

In the public interface for Query, we declare, but cannot yet define, the constructor that takes a string. That constructor creates a WordQuery object, so we cannot define this constructor until we have defined the WordQuery class.

The other two public members represent the interface for Query_base. In each case, the Query operation uses its Query_base pointer to call the respective (virtual) Query_base operation. The actual version that is called is determined at run time and will depend on the type of the object to which q points.

The Query Output Operator

The output operator is a good example of how our overall query system works:

Click here to view code image

```
std::ostream &
operator<<(std::ostream &os, const Query &query)
{
    // Query::rep makes a virtual call through its Query_base pointer to rep()
    return os << query.rep();
}</pre>
```

When we print a Query, the output operator calls the (public) rep member of class Query. That function makes a virtual call through its pointer member to the rep member of the object to which this Query points. That is, when we write

Click here to view code image

```
Query andq = Query(sought1) & Query(sought2);
cout << andq << endl;</pre>
```

the output operator calls <code>Query::rep</code> on <code>andq.Query::rep</code> in turn makes a virtual call through its <code>Query_base</code> pointer to the <code>Query_base</code> version of <code>rep</code>. Because <code>andq</code> points to an <code>AndQuery</code> object, that call will run <code>AndQuery::rep</code>.

Exercises Section 15.9.2

Exercise 15.32: What happens when an object of type Query is copied, moved, assigned, and destroyed?

15.9.3. The Derived Classes

The most interesting part of the classes derived from Query_base is how they are represented. The WordQuery class is most straightforward. Its job is to hold the search word.

The other classes operate on one or two operands. A NotQuery has a single operand, and AndQuery and OrQuery have two operands. In each of these classes, the operand(s) can be an object of any of the concrete classes derived from Query_base: A NotQuery can be applied to a WordQuery, an AndQuery, an OrQuery, or another NotQuery. To allow this flexibility, the operands must be stored as pointers to Query_base. That way we can bind the pointer to whichever concrete class we need.

However, rather than storing a Query_base pointer, our classes will themselves use a Query object. Just as user code is simplified by using the interface class, we can simplify our own class code by using the same class.

Now that we know the design for these classes, we can implement them.

The WordQuery Class

A WordQuery looks for a given string. It is the only operation that actually performs a query on the given TextQuery object:

Click here to view code image

Like Query_base, WordQuery has no public members; WordQuery must make Query a friend in order to allow Query to access the WordQuery constructor.

Each of the concrete query classes must define the inherited pure virtual functions, eval and rep. We defined both operations inside the WordQuery class body: eval calls the query member of its given TextQuery parameter, which does the actual search in the file; rep returns the string that this WordQuery represents (i.e., query_word).

Having defined the WordQuery class, we can now define the Query constructor that takes a string:

Click here to view code image

```
inline
Query::Query(const std::string &s): q(new WordQuery(s)) { }
```

This constructor allocates a WordQuery and initializes its pointer member to point to that newly allocated object.

The NotQuery Class and the ~ Operator

The ~ operator generates a NotQuery, which holds a Query, which it negates:

Click here to view code image

Because the members of NotQuery are all private, we start by making the ~ operator a friend. To rep a NotQuery, we concatenate the ~ symbol to the representation of the underlying Query. We parenthesize the output to ensure that precedence is clear to the reader.

It is worth noting that the call to rep in NotQuery's own rep member ultimately makes a virtual call to rep: query.rep() is a nonvirtual call to the rep member of the Query class. Query::rep in turn calls q->rep(), which is a virtual call through its Query_base pointer.

The ~ operator dynamically allocates a new NotQuery object. The return (implicitly) uses the Query constructor that takes a shared_ptr<Query_base>. That is, the return statement is equivalent to

```
// allocate a new NotQuery object
// bind the resulting NotQuery pointer to a shared_ptr<Query_base
shared_ptr<Query_base> tmp(new NotQuery(expr));
```

```
return Query(tmp); // use the Query constructor that takes a shared ptr
```

The eval member is complicated enough that we will implement it outside the class body. We'll define the eval functions in §15.9.4 (p. 647).

The BinaryQuery Class

The BinaryQuery class is an abstract base class that holds the data needed by the query types that operate on two operands:

Click here to view code image

The data in a BinaryQuery are the two Query operands and the corresponding operator symbol. The constructor takes the two operands and the operator symbol, each of which it stores in the corresponding data members.

To rep a BinaryOperator, we generate the parenthesized expression consisting of the representation of the left-hand operand, followed by the operator, followed by the representation of the right-hand operand. As when we displayed a NotQuery, the calls to rep ultimately make virtual calls to the rep function of the Query_base objects to which lhs and rhs point.

Note

The BinaryQuery class does not define the eval function and so inherits a pure virtual. Thus, BinaryQuery is also an abstract base class, and we cannot create objects of BinaryQuery type.

The AndQuery and OrQuery Classes and Associated Operators

The AndQuery and OrQuery classes, and their corresponding operators, are quite similar to one another:

Click here to view code image

```
class AndQuery: public BinaryQuery {
    friend Query operator& (const Query&, const Query&);
    AndQuery(const Query &left, const Query &right):
                         BinaryQuery(left, right, "&") { }
    // concrete class: AndQuery inherits rep and defines the remaining pure virtual
    QueryResult eval(const TextQuery&) const;
};
inline Query operator&(const Query &lhs, const Query &rhs)
        return std::shared ptr<Query base>(new AndQuery(lhs,
rhs));
class OrQuery: public BinaryQuery {
    friend Query operator (const Query&, const Query&);
    OrQuery(const Query &left, const Query &right):
                 BinaryQuery(left, right, "|") { }
    QueryResult eval(const TextQuery&) const;
};
inline Query operator (const Query &lhs, const Query &rhs)
        return std::shared ptr<Query base>(new OrQuery(lhs,
rhs));
```

These classes make the respective operator a friend and define a constructor to create their BinaryQuery base part with the appropriate operator. They inherit the BinaryQuery definition of rep, but each overrides the eval function.

Like the ~ operator, the & and | operators return a shared_ptr bound to a newly allocated object of the corresponding type. That shared_ptr gets converted to Query as part of the return statement in each of these operators.

Exercises Section 15.9.3

Exercise 15.34: For the expression built in Figure 15.3 (p. 638):

- (a) List the constructors executed in processing that expression.
- (b) List the calls to rep that are made from cout << q.
- (c) List the calls to eval made from q.eval().

Exercise 15.35: Implement the Query and Query_base classes, including a definition of rep but omitting the definition of eval.

Exercise 15.36: Put print statements in the constructors and rep members and run your code to check your answers to (a) and (b) from the first exercise.

Exercise 15.37: What changes would your classes need if the derived classes had members of type shared_ptr<Query_base> rather than of

```
type Query?
```

Exercise 15.38: Are the following declarations legal? If not, why not? If so, explain what the declarations mean.

Click here to view code image

```
BinaryQuery a = Query("fiery") & Query("bird");
AndQuery b = Query("fiery") & Query("bird");
OrQuery c = Query("fiery") & Query("bird");
```

15.9.4. The eval Functions

The eval functions are the heart of our guery system. Each of these functions calls eval on its operand(s) and then applies its own logic: The OrQuery eval operation returns the union of the results of its two operands; AndQuery returns the intersection. The NotQuery is more complicated: It must return the line numbers that are not in its operand's set.

To support the processing in the eval functions, we need to use the version of QueryResult that defines the members we added in the exercises to §12.3.2 (p. 490). We'll assume that QueryResult has begin and end members that will let us iterate through the set of line numbers that the QueryResult holds. We'll also assume that QueryResult has a member named get file that returns a shared_ptr to the underlying file on which the query was executed.

Warning

Our Query classes use members defined for QueryResult in the exercises to §12.3.2 (p. 490).

OrQuery::eval

An orquery represents the union of the results for its two operands, which we obtain by calling eval on each of its operands. Because these operands are Query objects, calling eval is a call to Query::eval, which in turn makes a virtual call to eval on the underlying Query_base object. Each of these calls yields a QueryResult representing the line numbers in which its operand appears. We'll combine those line numbers into a new set:

```
// returns the union of its operands' result sets
OueryResult
OrQuery::eval(const TextQuery& text) const
```

```
{
    // virtual calls through the Query members, lhs and rhs
    // the calls to eval return the QueryResult for each operand
    auto right = rhs.eval(text), left = lhs.eval(text);
    // copy the line numbers from the left-hand operand into the result set
    auto ret_lines =
        make_shared<set<line_no>>(left.begin(), left.end());
    // insert lines from the right-hand operand
    ret_lines->insert(right.begin(), right.end());
    // return the new QueryResult representing the union of lhs and rhs
    return QueryResult(rep(), ret_lines, left.get_file());
}
```

We initialize ret_lines using the set constructor that takes a pair of iterators. The begin and end members of a QueryResult return iterators into that object's set of line numbers. So, ret_lines is created by copying the elements from left's set. We next call insert on ret_lines to insert the elements from right. After this call, ret_lines contains the line numbers that appear in either left or right.

The eval function ends by building and returning a QueryResult representing the combined match. The QueryResult constructor (§12.3.2, p. 489) takes three arguments: a string representing the query, a shared_ptr to the set of matching line numbers, and a shared_ptr to the vector that represents the input file. We call rep to generate the string and get_file to obtain the shared_ptr to the file. Because both left and right refer to the same file, it doesn't matter which of these we use for get_file.

AndQuery::eval

The AndQuery version of eval is similar to the OrQuery version, except that it calls a library algorithm to find the lines in common to both queries:

}

Here we use the library set_intersection algorithm, which is described in Appendix A.2.8 (p. 880), to merge these two sets.

The set_intersection algorithm takes five iterators. It uses the first four to denote two input sequences (§10.5.2, p. 413). Its last argument denotes a destination. The algorithm writes the elements that appear in both input sequences into the destination.

In this call we pass an insert iterator (§10.4.1, p. 401) as the destination. When set_intersection writes to this iterator, the effect will be to insert a new element into ret_lines.

Like the OrQuery eval function, this one ends by building and returning a QueryResult representing the combined match.

NotQuery::eval

NotQuery finds each line of the text within which the operand is not found:

Click here to view code image

```
// returns the lines not in its operand's result set
OueryResult
NotQuery::eval(const TextQuery& text) const
     // virtual call to eval through the Query operand
     auto result = query.eval(text);
     // start out with an empty result set
     auto ret_lines = make_shared<set<line_no>>();
     // we have to iterate through the lines on which our operand appears
     auto beg = result.begin(), end = result.end();
     // for each line in the input file, if that line is not in result,
     // add that line number to ret lines
     auto sz = result.get_file()->size();
     for (size_t n = 0; n != sz; ++n) {
          // if we haven't processed all the lines in result
          // check whether this line is present
          if (beg == end || *beg != n)
               ret_lines->insert(n); // if not in result, add this line
          else if (beg != end)
               ++beg; // otherwise get the next line number in result if there is
one
     return QueryResult(rep(), ret_lines, result.get_file());
```

As in the other eval functions, we start by calling eval on this object's operand. That call returns the <code>QueryResult</code> containing the line numbers on which the operand

appears, but we want the line numbers on which the operand does not appear. That is, we want every line in the file that is not already in result.

We generate that set by iterating through sequenital integers up to the size of the input file. We'll put each number that is not in result into ret_lines. We position beg and end to denote the first and one past the last elements in result. That object is a set, so when we iterate through it, we'll obtain the line numbers in ascending order.

The loop body checks whether the current number is in result. If not, we add that number to ret_lines. If the number is in result, we increment beg, which is our iterator into result.

Once we've processed all the line numbers, we return a QueryResult containing ret_lines, along with the results of running rep and get_file as in the previous eval functions.

Exercises Section 15.9.4

Exercise 15.39: Implement the Query and Query_base classes. Test your application by evaluating and printing a query such as the one in Figure 15.3 (p. 638).

Exercise 15.40: In the OrQuery eval function what would happen if its rhs member returned an empty set? What if its lhs member did so? What if both rhs and lhs returned empty sets?

Exercise 15.41: Reimplement your classes to use built-in pointers to Query_base rather than shared_ptrs. Remember that your classes will no longer be able to use the synthesized copy-control members.

Exercise 15.42: Design and implement one of the following enhancements:

- (a) Print words only once per sentence rather than once per line.
- **(b)** Introduce a history system in which the user can refer to a previous query by number, possibly adding to it or combining it with another.
- (c) Allow the user to limit the results so that only matches in a given range of lines are displayed.

Chapter Summary

Inheritance lets us write new classes that share behavior with their base class(es) but override or add to that behavior as needed. Dynamic binding lets us ignore type differences by choosing, at run time, which version of a function to run based on an object's dynamic type. The combination of inheritance and dynamic binding lets us write type-independent, programs that have type-specific behavior.

In C++, dynamic binding applies *only* to functions declared as virtual and called through a reference or pointer.

A derived-class object contains a subobject corresponding to each of its base classes. Because every derived object contains a base part, we can convert a reference or pointer to a derived-class type to a reference or pointer to an accessible base class.

Inherited objects are constructed, copied, moved, and assigned by constructing, copying, moving, and assigning the base part(s) of the object before handling the derived part. Destructors execute in the opposite order; the derived type is destroyed first, followed by destructors for the base-class subobjects. Base classes usually should define a virtual destructor even if the class otherwise has no need for a destructor. The destructor must be virtual if a pointer to a base is ever deleted when it actually addresses a derived-class object.

A derived class specifies a protection level for each of its base class(es). Members of a public base are part of the interface of the derived class; members of a private base are inaccessible; members of a protected base are accessible to classes that derive from the derived class but not to users of the derived class.

Defined Terms

abstract base class Class that has one or more pure virtual functions. We cannot create objects of an abstract base-class type.

accessible Base class member that can be used through a derived object. Accessibility depends on the access specifier used in derivation list of the derived class and the access level of the member in the base class. For example, a public member of a class that is inherited via public inheritance is accessible to users of the derived class. A public base class member is inacceessible if the inheritance is private.

base class Class from which other classes inherit. The members of the base class become members of the derived class.

class derivation list List of base classes, each of which may have an optional access level, from which a derived class inherits. If no access specifier is provided, the inheritance is public if the derived class is defined with the struct keyword, and is private if the class is defined with the class keyword.

derived class Class that inherits from another class. A derived class can override the virtuals of its base and can define new members. A derived-class scope is nested in the scope of its base class(es); members of the derived class can use members of the base class directly.

derived-to-base conversion Implicit conversion of a derived object to a reference to a base class, or of a pointer to a derived object to a pointer to the base type.

direct base class Base class from which a derived class inherits directly. Direct base classes are specified in the derivation list of the derived class. A direct base class may itself be a derived class.

dynamic binding Delaying until run time the selection of which function to run. In C++, dynamic binding refers to the runtime choice of which virtual function to run based on the underlying type of the object to which a reference or pointer is bound.

dynamic type Type of an object at run time. The dynamic type of an object to which a reference refers or to which a pointer points may differ from the static type of the reference or pointer. A pointer or reference to a base-class type can refer to an to object of derived type. In such cases the static type is reference (or pointer) to base, but the dynamic type is reference (or pointer) to derived.

indirect base class Base class that does not appear in the derivation list of a derived class. A class from which the direct base class inherits, directly or indirectly, is an indirect base class to the derived class.

inheritance Programming technique for defining a new class (known as a derived class) in terms of an existing class (known as the base class). The derived class inherits the members of the base class.

object-oriented programming Method of writing programs using data abstraction, inheritance, and dynamic binding.

override Virtual function defined in a derived class that has the same parameter list as a virtual in a base class overrides the base-class definition.

polymorphism As used in object-oriented programming, refers to the ability to obtain type-specific behavior based on the dynamic type of a reference or pointer.

private inheritance In private inheritance, the public and protected members of the base class are private members of the derived.

protected access specifier Members defined after the protected keyword may be accessed by the members and friends of a derived class. However, these members are only accessible through derived objects. protected members are not accessible to ordinary users of the class.

protected inheritance In protected inheritance, the protected and public members of the base class are protected members of the derived class.

public inheritance The public interface of the base class is part of the public interface of the derived class.

pure virtual Virtual function declared in the class header using = 0 just before the semicolon. A pure virtual function need not be (but may be) defined. Classes with pure virtuals are abstract classes. If a derived class does not define its own version of an inherited pure virtual, then the derived class is abstract as well.

refactoring Redesigning programs to collect related parts into a single abstraction, replacing the original code with uses of the new abstraction. Typically, classes are refactored to move data or function members to the highest common point in the hierarchy to avoid code duplication.

run-time binding See dynamic binding.

sliced down What happens when an object of derived type is used to initialize or assign an object of the base type. The derived portion of the object is "sliced down," leaving only the base portion, which is assigned to the base.

static type Type with which a variable is defined or that an expression yields. Static type is known at compile time.

virtual function Member function that defines type-specific behavior. Calls to a virtual made through a reference or pointer are resolved at run time, based on the type of the object to which the reference or pointer is bound.

Chapter Summary

Defined Terms

Both object-oriented programming (OOP) and generic programming deal with types that are not known at the time the program is written. The distinction between the two is that OOP deals with types that are not known until run time, whereas in generic programming the types become known during compilation.

The containers, iterators, and algorithms described in Part II are all examples of generic programming. When we write a generic program, we write the code in a way

that is independent of any particular type. When we use a generic program, we supply the type(s) or value(s) on which that instance of the program will operate.

For example, the library provides a single, generic definition of each container, such as vector. We can use that generic definition to define many different types of vectors, each of which differs from the others as to the type of elements the vector contains.

Templates are the foundation of generic programming. We can use and have used templates without understanding how they are defined. In this chapter we'll see how to define our own templates.

Templates are the foundation for generic programming in C++. A template is a blueprint or formula for creating classes or functions. When we use a generic type, such as vector, or a generic function, such as find, we supply the information needed to transform that blueprint into a specific class or function. That transformation happens during compilation. In Chapter 3 and Part II we learned how to use templates. In this chapter we'll learn how to define them.

16.1. Defining a Template

Imagine that we want to write a function to compare two values and indicate whether the first is less than, equal to, or greater than the second. In practice, we'd want to define several such functions, each of which will compare values of a given type. Our first attempt might be to define several overloaded functions:

Click here to view code image

```
// returns 0 if the values are equal, -1 if v1 is smaller, 1 if v2 is smaller
int compare(const string &v1, const string &v2)
{
    if (v1 < v2) return -1;
    if (v2 < v1) return 1;
    return 0;
}
int compare(const double &v1, const double &v2)
{
    if (v1 < v2) return -1;
    if (v2 < v1) return 1;
    return 0;
}</pre>
```

These functions are nearly identical: The only difference between them is the type of their parameters. The function body is the same in each function.

Having to repeat the body of the function for each type that we compare is tedious and error-prone. More importantly, we need to know when we write the program all the types that we might ever want to compare. This strategy cannot work if we want to be able to use the function on types that our users might supply.

16.1.1. Function Templates

Rather than defining a new function for each type, we can define a **function template**. A function template is a formula from which we can generate type-specific versions of that function. The template version of compare looks like

Click here to view code image

```
template <typename T>
int compare(const T &v1, const T &v2)
{
   if (v1 < v2) return -1;
   if (v2 < v1) return 1;
   return 0;
}</pre>
```

A template definition starts with the keyword template followed by a **template parameter list**, which is a comma-separated list of one or more **template parameters** bracketed by the less-than (<) and greater-than (>) tokens.

Note

In a template definition, the template parameter list cannot be empty.

The template parameter list acts much like a function parameter list. A function parameter list defines local variable(s) of a specified type but does not say how to initialize them. At run time, arguments are supplied that initialize the parameters.

Analogously, template parameters represent types or values used in the definition of a class or function. When we use a template, we specify—either implicitly or explicitly—template argument(s) to bind to the template parameter(s).

Our compare function declares one type parameter named T. Inside compare, we use the name T to refer to a type. Which actual type T represents is determined at compile time based on how compare is used.

Instantiating a Function Template

When we call a function template, the compiler (ordinarily) uses the arguments of the call to deduce the template argument(s) for us. That is, when we call compare, the compiler uses the type of the arguments to determine what type to bind to the template parameter T. For example, in this call

```
cout << compare(1, 0) << endl; // T is int
```

the arguments have type int. The compiler will deduce int as the template argument and will bind that argument to the template parameter T.

The compiler uses the deduced template parameter(s) to **instantiate** a specific version of the function for us. When the compiler instantiates a template, it creates a new "instance" of the template using the actual template argument(s) in place of the corresponding template parameter(s). For example, given the calls

Click here to view code image

the compiler will instantiate two different versions of compare. For the first call, the compiler will write and compile a version of compare with T replaced by int:

Click here to view code image

```
int compare(const int &v1, const int &v2)
{
    if (v1 < v2) return -1;
    if (v2 < v1) return 1;
    return 0;
}</pre>
```

For the second call, it will generate a version of compare with T replaced by vector<int>. These compiler-generated functions are generally referred to as an instantiation of the template.

Template Type Parameters

Our compare function has one template **type parameter**. In general, we can use a type parameter as a type specifier in the same way that we use a built-in or class type specifier. In particular, a type parameter can be used to name the return type or a function parameter type, and for variable declarations or casts inside the function body:

```
// ok: same type used for the return type and parameter
template <typename T> T foo(T* p)
{
    T tmp = *p; // tmp will have the type to which p points
    // ...
    return tmp;
}
```

Each type parameter must be preceded by the keyword class or typename:

Click here to view code image

```
// error: must precede U with either typename or class
template <typename T, U> T calc(const T&, const U&);
```

These keywords have the same meaning and can be used interchangeably inside a template parameter list. A template parameter list can use both keywords:

Click here to view code image

```
// ok: no distinction between typename and class in a template parameter list
template <typename T, class U> calc (const T&, const U&);
```

It may seem more intuitive to use the keyword typename rather than class to designate a template type parameter. After all, we can use built-in (nonclass) types as a template type argument. Moreover, typename more clearly indicates that the name that follows is a type name. However, typename was added to C++ after templates were already in widespread use; some programmers continue to use class exclusively.

Nontype Template Parameters

In addition to defining type parameters, we can define templates that take **nontype parameters**. A nontype parameter represents a value rather than a type. Nontype parameters are specified by using a specific type name instead of the class or typename keyword.

When the template is instantiated, nontype parameters are replaced with a value supplied by the user or deduced by the compiler. These values must be constant expressions (§ 2.4.4, p. 65), which allows the compiler to instantiate the templates during compile time.

As an example, we can write a version of compare that will handle string literals. Such literals are arrays of const char. Because we cannot copy an array, we'll define our parameters as references to an array (§ 6.2.4, p. 217). Because we'd like to be able to compare literals of different lengths, we'll give our template two nontype parameters. The first template parameter will represent the size of the first array, and the second parameter will represent the second array:

Click here to view code image

```
template<unsigned N, unsigned M>
int compare(const char (&p1)[N], const char (&p2)[M])
{
   return strcmp(p1, p2);
}
```

When we call this version of compare:

```
compare("hi", "mom")
```

the compiler will use the size of the literals to instantiate a version of the template with the sizes substituted for N and M. Remembering that the compiler inserts a null terminator at the end of a string literal (§ 2.1.3, p. 39), the compiler will instantiate

Click here to view code image

```
int compare(const char (&p1)[3], const char (&p2)[4])
```

A nontype parameter may be an integral type, or a pointer or (Ivalue) reference to an object or to a function type. An argument bound to a nontype integral parameter must be a constant expression. Arguments bound to a pointer or reference nontype parameter must have static lifetime (Chapter 12, p. 450). We may not use an ordinary (nonstatic) local object or a dynamic object as a template argument for reference or pointer nontype template parameters. A pointer parameter can also be instantiated by nullptr or a zero-valued constant expression.

A template nontype parameter is a constant value inside the template definition. A nontype parameter can be used when constant expressions are required, for example, to specify the size of an array.

Note

Template arguments used for nontype template parameters must be constant expressions.

inline and constexpr Function Templates

A function template can be declared inline or constexpr in the same ways as nontemplate functions. The inline or constexpr specifier follows the template parameter list and precedes the return type:

Click here to view code image

```
// ok: inline specifier follows the template parameter list
template <typename T> inline T min(const T&, const T&);
// error: incorrect placement of the inline specifier
inline template <typename T> T min(const T&, const T&);
```

Writing Type-Independent Code

Simple though it is, our initial compare function illustrates two important principles for writing generic code:

• The function parameters in the template are references to const.

The tests in the body use only < comparisons.

By making the function parameters references to const, we ensure that our function can be used on types that cannot be copied. Most types—including the built-in types and, except for unique_ptr and the IO types, all the library types we've used—do allow copying. However, there can be class types that do not allow copying. By making our parameters references to const, we ensure that such types can be used with our compare function. Moreover, if compare is called with large objects, then this design will also make the function run faster.

You might think it would be more natural for the comparisons to be done using both the < and > operators:

```
// expected comparison
if (v1 < v2) return -1;
if (v1 > v2) return 1;
return 0;
```

However, by writing the code using only the < operator, we reduce the requirements on types that can be used with our compare function. Those types must support <, but they need not also support >.

In fact, if we were truly concerned about type independence and portability, we probably should have defined our function using the less (§ 14.8.2, p. 575):

Click here to view code image

```
// version of compare that will be correct even if used on pointers; see § 14.8.2 (p.
575)
template <typename T> int compare(const T &v1, const T &v2)
    if (less<T>()(v1, v2)) return -1;
    if (less<T>()(v2, v1)) return 1;
    return 0;
```

The problem with our original version is that if a user calls it with two pointers and those pointers do not point to the same array, then our code is undefined.

Best Practices

Template programs should try to minimize the number of requirements placed on the argument types.

Template Compilation

When the compiler sees the definition of a template, it does not generate code. It

generates code only when we instantiate a specific instance of the template. The fact that code is generated only when we use a template (and not when we define it) affects how we organize our source code and when errors are detected.

Ordinarily, when we call a function, the compiler needs to see only a declaration for the function. Similarly, when we use objects of class type, the class definition must be available, but the definitions of the member functions need not be present. As a result, we put class definitions and function declarations in header files and definitions of ordinary and class-member functions in source files.

Templates are different: To generate an instantiation, the compiler needs to have the code that defines a function template or class template member function. As a result, unlike nontemplate code, headers for templates typically include definitions as well as declarations

Definitions of function templates and member functions of class templates are ordinarily put into header files.

Key Concept: Templates and Headers

Templates contain two kinds of names:

- Those that do not depend on a template parameter
- Those that do depend on a template parameter

It is up to the provider of a template to ensure that all names that do not depend on a template parameter are visible when the template is used. Moreover, the template provider must ensure that the definition of the template, including the definitions of the members of a class template, are visible when the template is instantiated.

It is up to users of a template to ensure that declarations for all functions, types, and operators associated with the types used to instantiate the template are visible.

Both of these requirements are easily satisfied by well-structured programs that make appropriate use of headers. Authors of templates should provide a header that contains the template definition along with declarations for all the names used in the class template or in the definitions of its members. Users of the template must include the header for the template and for any types used to instantiate that template.

The fact that code is not generated until a template is instantiated affects when we learn about compilation errors in the code inside the template. In general, there are three stages during which the compiler might flag an error.

The first stage is when we compile the template itself. The compiler generally can't find many errors at this stage. The compiler can detect syntax errors—such as forgetting a semicolon or misspelling a variable name—but not much else.

The second error-detection time is when the compiler sees a use of the template. At this stage, there is still not much the compiler can check. For a call to a function template, the compiler typically will check that the number of the arguments is appropriate. It can also detect whether two arguments that are supposed to have the same type do so. For a class template, the compiler can check that the right number of template arguments are provided but not much more.

The third time when errors are detected is during instantiation. It is only then that type-related errors can be found. Depending on how the compiler manages instantiation, these errors may be reported at link time.

When we write a template, the code may not be overtly type specific, but template code usually makes some assumptions about the types that will be used. For example, the code inside our original compare function:

Click here to view code image

```
if (v1 < v2) return -1; // requires < on objects of type T if (v2 < v1) return 1; // requires < on objects of type T return 0; // returns int; not dependent on T
```

assumes that the argument type has a < operator. When the compiler processes the body of this template, it cannot verify whether the conditions in the if statements are legal. If the arguments passed to compare have a < operation, then the code is fine, but not otherwise. For example,

Click here to view code image

```
Sales_data data1, data2;
cout << compare(data1, data2) << endl; // error: no < on
Sales data</pre>
```

This call instantiates a version of compare with T replaced by Sales_data. The if conditions attempt to use < on Sales_data objects, but there is no such operator. This instantiation generates a version of the function that will not compile. However, errors such as this one cannot be detected until the compiler instantiates the definition of compare on type Sales_data.

It is up to the caller to guarantee that the arguments passed to the template

support any operations that template uses, and that those operations behave correctly in the context in which the template uses them.

Exercises Section 16.1.1

Exercise 16.1: Define instantiation.

Exercise 16.2: Write and test your own versions of the compare functions.

Exercise 16.3: Call your compare function on two Sales_data objects to see how your compiler handles errors during instantiation.

Exercise 16.4: Write a template that acts like the library find algorithm. The function will need two template type parameters, one to represent the function's iterator parameters and the other for the type of the value. Use your function to find a given value in a vector<int> and in a list<string>.

Exercise 16.5: Write a template version of the print function from § 6.2.4 (p. 217) that takes a reference to an array and can handle arrays of any size and any element type.

Exercise 16.6: How do you think the library begin and end functions that take an array argument work? Define your own versions of these functions.

Exercise 16.7: Write a constexpr template that returns the size of a given array.

Exercise 16.8: In the "Key Concept" box on page 108, we noted that as a matter of habit C++ programmers prefer using != to using <. Explain the rationale for this habit.

16.1.2. Class Templates

A class template is a blueprint for generating classes. Class templates differ from function templates in that the compiler cannot deduce the template parameter type(s) for a class template. Instead, as we've seen many times, to use a class template we must supply additional information inside angle brackets following the template's name (§ 3.3, p. 97). That extra information is the list of template arguments to use in place of the template parameters.

Defining a Class Template

As an example, we'll implement a template version of StrBlob (§ 12.1.1, p. 456). We'll name our template Blob to indicate that it is no longer specific to strings.

Like StrBlob, our template will provide shared (and checked) access to the elements it holds. Unlike that class, our template can be used on elements of pretty much any type. As with the library containers, our users will have to specify the element type when they use a Blob.

Like function templates, class templates begin with the keyword template followed by a template parameter list. In the definition of the class template (and its members), we use the template parameters as stand-ins for types or values that will be supplied when the template is used:

Click here to view code image

```
template <typename T> class Blob {
public:
    typedef T value_type;
    typedef typename std::vector<T>::size_type size_type;
    // constructors
    Blob();
    Blob(std::initializer_list<T> il);
    // number of elements in the Blob
    size_type size() const { return data->size(); }
    bool empty() const { return data->empty(); }
    // add and remove elements
    void push_back(const T &t) {data->push_back(t);}
    // move version; see § 13.6.3 (p. 548)
    void push_back(T &&t) { data->push_back(std::move(t)); }
    void pop_back();
    // element access
    T& back();
    T& operator[](size_type i); // defined in § 14.5 (p. 566)
private:
    std::shared ptr<std::vector<T>> data;
    // throws msg if data[i] isn't valid
    void check(size_type i, const std::string &msg) const;
};
```

Our Blob template has one template type parameter, named T. We use the type parameter anywhere we refer to the element type that the Blob holds. For example, we define the return type of the operations that provide access to the elements in the Blob as T&. When a user instantiates a Blob, these uses of T will be replaced by the specified template argument type.

With the exception of the template parameter list, and the use of T instead of string, this class is the same as the version we defined in § 12.1.1 (p. 456) and updated in § 12.1.6 (p. 475) and in Chapters 13 and 14.

Instantiating a Class Template

As we've seen many times, when we use a class template, we must supply extra

information. We can now see that that extra information is a list of explicit template arguments that are bound to the template's parameters. The compiler uses these template arguments to instantiate a specific class from the template.

For example, to define a type from our Blob template, we must provide the element type:

Click here to view code image

```
Blob<int> ia;
                                  // empty Blob<int>
Blob<int> ia2 = \{0,1,2,3,4\}; // Blob<int> with five elements
```

Both ia and ia2 use the same type-specific version of Blob (i.e., Blob<int>). From these definitions, the compiler will instantiate a class that is equivalent to

Click here to view code image

```
template <> class Blob<int> {
    typedef typename std::vector<int>::size_type size_type;
    Blob();
    Blob(std::initializer_list<int> il);
    int& operator[](size_type i);
private:
    std::shared_ptr<std::vector<int>> data;
    void check(size_type i, const std::string &msg) const;
};
```

When the compiler instantiates a class from our Blob template, it rewrites the Blob template, replacing each instance of the template parameter T by the given template argument, which in this case is int.

The compiler generates a different class for each element type we specify:

Click here to view code image

```
// these definitions instantiate two distinct Blob types
Blob<string> names; // Blob that holds strings
Blob<double> prices;// different element type
```

These definitions would trigger instantiations of two distinct classes: The definition of names creates a Blob class in which each occurrence of T is replaced by string. The definition of prices generates a Blob with T replaced by double.

Each instantiation of a class template constitutes an independent class. The type Blob<string> has no relationship to, or any special access to, the members of any other Blob type.

References to a Template Type in the Scope of the Template

In order to read template class code, it can be helpful to remember that the name of a class template is not the name of a type (§ 3.3, p. 97). A class template is used to instantiate a type, and an instantiated type always includes template argument(s).

What can be confusing is that code in a class template generally doesn't use the name of an actual type (or value) as a template argument. Instead, we often use the template's own parameter(s) as the template argument(s). For example, our data member uses two templates, vector and shared_ptr. Whenever we use a template, we must supply template arguments. In this case, the template argument we supply is the same type that is used to instantiate the Blob. Therefore, the definition of data

Click here to view code image

```
std::shared_ptr<std::vector<T>> data;
```

uses Blob's type parameter to say that data is the instantiation of shared_ptr that points to the instantiation of vector that holds objects of type T. When we instantiate a particular kind of Blob, such as Blob<string>, then data will be

Click here to view code image

```
shared_ptr<vector<string>>
```

If we instantiate Blob<int>, then data will be shared_ptr<vector<int>>, and so on.

Member Functions of Class Templates

As with any class, we can define the member functions of a class template either inside or outside of the class body. As with any other class, members defined inside the class body are implicitly inline.

A class template member function is itself an ordinary function. However, each instantiation of the class template has its own version of each member. As a result, a member function of a class template has the same template parameters as the class itself. Therefore, a member function defined outside the class template body starts with the keyword template followed by the class' template parameter list.

As usual, when we define a member outside its class, we must say to which class the member belongs. Also as usual, the name of a class generated from a template includes its template arguments. When we define a member, the template argument(s) are the same as the template parameter(s). That is, for a given member function of StrBlob that was defined as

```
ret-type StrBlob::member-name(parm-list)
```

the corresponding Blob member will look like

Click here to view code image

```
template <typename T>
ret-type Blob<T>::member-name(parm-list)
```

The check and Element Access Members

We'll start by defining the check member, which verifies a given index:

Click here to view code image

```
template <typename T>
void Blob<T>::check(size_type i, const std::string &msg)
const
{
    if (i >= data->size())
        throw std::out_of_range(msg);
}
```

Aside from the differences in the class name and the use of the template parameter list, this function is identical to the original StrBlob member.

The subscript operator and back function use the template parameter to specify the return type but are otherwise unchanged:

Click here to view code image

```
template <typename T>
T& Blob<T>::back()
{
    check(0, "back on empty Blob");
    return data->back();
}
template <typename T>
T& Blob<T>::operator[](size_type i)
{
    // if i is too big, check will throw, preventing access to a nonexistent element check(i, "subscript out of range");
    return (*data)[i];
}
```

In our original StrBlob class these operators returned string&. The template versions will return a reference to whatever type is used to instantiate Blob.

The pop_back function is nearly identical to our original StrBlob member:

```
template <typename T> void Blob<T>::pop_back()
```

```
{
    check(0, "pop_back on empty Blob");
    data->pop_back();
}
```

The subscript operator and back members are overloaded on const. We leave the definition of these members, and of the front members, as an exercise.

Blob Constructors

As with any other member defined outside a class template, a constructor starts by declaring the template parameters for the class template of which it is a member:

Click here to view code image

```
template <typename T>
Blob<T>::Blob(): data(std::make_shared<std::vector<T>>()) { }
```

Here we are defining the member named Blob in the scope of Blob<T>. Like our StrBlob default constructor (§ 12.1.1, p. 456), this constructor allocates an empty vector and stores the pointer to that vector in data. As we've seen, we use the class' own type parameter as the template argument of the vector we allocate.

Similarly, the constructor that takes an initializer_list uses its type parameter T as the element type for its initializer_list parameter:

Click here to view code image

Like the default constructor, this constructor allocates a new vector. In this case, we initialize that vector from the parameter, il.

To use this constructor, we must pass an initializer_list in which the elements are compatible with the element type of the Blob:

Click here to view code image

```
Blob<string> articles = { "a", "an", "the" };
```

The parameter in this constructor has type initializer_list<string>. Each string literal in the list is implicitly converted to string.

Instantiation of Class-Template Member Functions

By default, a member function of a class template is instantiated only if the program uses that member function. For example, this code

```
instantiates Blob<int> and the initializer_list<int> constructor
Blob<int> squares = {0,1,2,3,4,5,6,7,8,9};
// instantiates Blob<int>::size() const
for (size_t i = 0; i != squares.size(); ++i)
    squares[i] = i*i; // instantiates Blob<int>::operator[](size_t)
```

instantiates the Blob<int> class and three of its member functions: operator[],
size, and the initializer_list<int> constructor.

If a member function isn't used, it is not instantiated. The fact that members are instantiated only if we use them lets us instantiate a class with a type that may not meet the requirements for some of the template's operations (§ 9.2, p. 329).

Note

By default, a member of an instantiated class template is instantiated only if the member is used.

Simplifying Use of a Template Class Name inside Class Code

There is one exception to the rule that we must supply template arguments when we use a class template type. Inside the scope of the class template itself, we may use the name of the template without arguments:

```
// BlobPtr throws an exception on attempts to access a nonexistent element
template <typename T> class BlobPtr
public:
    BlobPtr(): curr(0) { }
    BlobPtr(Blob<T> &a, size_t sz = 0):
              wptr(a.data), curr(sz) { }
    T& operator*() const
     { auto p = check(curr, "dereference past end");
       return (*p)[curr]; // (*p) is the vector to which this object points
    // increment and decrement
                                       // prefix operators
    BlobPtr& operator++();
    BlobPtr& operator--();
private:
    // check returns a shared_ptr to the vector if the check succeeds
    std::shared ptr<std::vector<T>>
         check(std::size_t, const std::string&) const;
    // store a weak_ptr, which means the underlying vector might be destroyed
    std::weak_ptr<std::vector<T>> wptr;
    std::size_t curr;
                             // current position within the array
};
```

Careful readers will have noted that the prefix increment and decrement members of BlobPtr return BlobPtr&, not BlobPtr<T>&. When we are inside the scope of a class template, the compiler treats references to the template itself as if we had supplied template arguments matching the template's own parameters. That is, it is as if we had written:

```
BlobPtr<T>& operator++();
BlobPtr<T>& operator--();
```

Using a Class Template Name outside the Class Template Body

When we define members outside the body of a class template, we must remember that we are not in the scope of the class until the class name is seen (§ 7.4, p. 282):

Click here to view code image

```
// postfix: increment/decrement the object but return the unchanged value
template <typename T>
BlobPtr<T> BlobPtr<T>::operator++(int)
{
    // no check needed here; the call to prefix increment will do the check
    BlobPtr ret = *this; // save the current value
    ++*this; // advance one element; prefix ++ checks the increment
    return ret; // return the saved state
}
```

Because the return type appears outside the scope of the class, we must specify that the return type returns a BlobPtr instantiated with the same type as the class. Inside the function body, we are in the scope of the class so do not need to repeat the template argument when we define ret. When we do not supply template arguments, the compiler assumes that we are using the same type as the member's instantiation. Hence, the definition of ret is as if we had written:

```
BlobPtr<T> ret = *this;
```

Note

Inside the scope of a class template, we may refer to the template without specifying template argument(s).

Class Templates and Friends

When a class contains a friend declaration (§ 7.2.1, p. 269), the class and the friend can independently be templates or not. A class template that has a nontemplate friend grants that friend access to all the instantiations of the template. When the friend is

itself a template, the class granting friendship controls whether friendship includes all instantiations of the template or only specific instantiation(s).

One-to-One Friendship

The most common form of friendship from a class template to another template (class or function) establishes friendship between corresponding instantiations of the class and its friend. For example, our Blob class should declare the BlobPtr class and a template version of the Blob equality operator (originally defined for StrBlob in the exercises in § 14.3.1 (p. 562)) as friends.

In order to refer to a specific instantiation of a template (class or function) we must first declare the template itself. A template declaration includes the template's template parameter list:

Click here to view code image

```
// forward declarations needed for friend declarations in Blob
template <typename> class BlobPtr;
template <typename> class Blob; // needed for parameters in operator==
template <typename T>
    bool operator==(const Blob<T>&, const Blob<T>&);
template <typename T> class Blob {
    // each instantiation of Blob grants access to the version of
    // BlobPtr and the equality operator instantiated with the same type
    friend class BlobPtr<T>;
    friend bool operator==<T>
        (const Blob<T>&, const Blob<T>&);
    // other members as in § 12.1.1 (p. 456)
};
```

We start by declaring that Blob, BlobPtr, and operator == are templates. These declarations are needed for the parameter declaration in the operator == function and the friend declarations in Blob.

The friend declarations use Blob's template parameter as their own template argument. Thus, the friendship is restricted to those instantiations of BlobPtr and the equality operator that are instantiated with the same type:

Click here to view code image

```
Blob<char> ca; // BlobPtr<char> and operator==<char> are friends
Blob<int> ia; // BlobPtr<int> and operator==<int> are friends
```

The members of BlobPtr<char> may access the nonpublic parts of ca (or any other Blob<char> object), but ca has no special access to ia (or any other Blob<int>) or to any other instantiation of Blob.

General and Specific Template Friendship

A class can also make every instantiation of another template its friend, or it may limit friendship to a specific instantiation:

Click here to view code image

```
// forward declaration necessary to be friend a specific instantiation of a template
template <typename T> class Pal;
class C \{ // C is an ordinary, nontemplate class
     friend class Pal<C>; // Pal instantiated with class C is a friend to
\boldsymbol{C}
     // all instances of Pal2 are friends to C;
     // no forward declaration required when we befriend all instantiations
     template <typename T> friend class Pal2;
};
template <typename T> class C2 { // C2 is itself a class template
     // each instantiation of C2 has the same instance of Pal as a friend
      friend class Pal<T>; // a template declaration for Pal must be in
scope
     // all instances of Pal2 are friends of each instance of C2, prior declaration
needed
     template <typename X> friend class Pal2;
     // Pal3 is a nontemplate class that is a friend of every instance of C2
     friend class Pal3;
                                // prior declaration for Pal3 not needed
};
```

To allow all instantiations as friends, the friend declaration must use template parameter(s) that differ from those used by the class itself.

Befriending the Template's Own Type Parameter

Under the new standard, we can make a template type parameter a friend:

Click here to view code image

Here we say that whatever type is used to instantiate Bar is a friend. Thus, for some type named Foo, Foo would be a friend of Bar<Foo>, Sales_data a friend of Bar<Sales data>, and so on.

It is worth noting that even though a friend ordinarily must be a class or a function, it is okay for Bar to be instantiated with a built-in type. Such friendship is allowed so that we can instantiate classes such as Bar with built-in types.

Template Type Aliases

An instantiation of a class template defines a class type, and as with any other class type, we can define a typedef (§ 2.5.1, p. 67) that refers to that instantiated class:

```
typedef Blob<string> StrBlob;
```

This typedef will let us run the code we wrote in § 12.1.1 (p. 456) using our template version of Blob instantiated with string. Because a template is not a type, we cannot define a typedef that refers to a template. That is, there is no way to define a typedef that refers to Blob<T>.

C++ 11

However, the new standard lets us define a type alias for a class template:

Click here to view code image

```
template<typename T> using twin = pair<T, T>;
twin<string> authors; // authors is a pair<string, string>
```

Here we've defined twin as a synonym for pairs in which the members have the same type. Users of twin need to specify that type only once.

A template type alias is a synonym for a family of classes:

Click here to view code image

```
twin<int> win_loss;  // win_loss is a pair<int, int>
twin<double> area;  // area is a pair<double, double>
```

Just as we do when we use a class template, when we use twin, we specify which particular kind of twin we want.

When we define a template type alias, we can fix one or more of the template parameters:

Click here to view code image

```
template <typename T> using partNo = pair<T, unsigned>;
partNo<string> books; // books is a pair<string, unsigned>
partNo<Vehicle> cars; // cars is a pair<Vehicle, unsigned>
partNo<Student> kids; // kids is a pair<Student, unsigned>
```

Here we've defined partNo as a synonym for the family of types that are pairs in which the second member is an unsigned. Users of partNo specify a type for the first member of the pair but have no choice about second.

static Members of Class Templates

Like any other class, a class template can declare static members (§ 7.6, p. 300):

Click here to view code image

```
template <typename T> class Foo {
public:
    static std::size_t count() { return ctr; }
    // other interface members
private:
    static std::size_t ctr;
    // other implementation members
};
```

Here Foo is a class template that has a public static member function named count and a private static data member named ctr. Each instantiation of Foo has its own instance of the static members. That is, for any given type X, there is one Foo<X>::ctr and one Foo<X>::count member. All objects of type Foo<X> share the same ctr object and count function. For example,

Click here to view code image

```
// instantiates static members Foo<string>::ctr and Foo<string>::count
Foo<string> fs;
// all three objects share the same Foo<int>::ctr and Foo<int>::count members
Foo<int> fi, fi2, fi3;
```

As with any other static data member, there must be exactly one definition of each static data member of a template class. However, there is a distinct object for each instantiation of a class template. As a result, we define a static data member as a template similarly to how we define the member functions of that template:

Click here to view code image

```
template <typename T>
size_t Foo<T>::ctr = 0; // define and initialize ctr
```

As with any other member of a class template, we start by defining the template parameter list, followed by the type of the member we are defining and the member's name. As usual, a member's name includes the member's class name, which for a class generated from a template includes its template arguments. Thus, when Foo is instantiated for a particular template argument type, a separate ctr will be instantiated for that class type and initialized to 0.

As with static members of nontemplate classes, we can access a static member of a class template through an object of the class type or by using the scope operator to access the member directly. Of course, to use a static member through the class, we must refer to a specific instantiation:

```
Foo<int> fi; // instantiates Foo<int> class // and the static data member ctr auto ct = Foo<int>::count(); // instantiates Foo<int>::count
```

Like any other member function, a static member function is instantiated only if it is used in a program.

Exercises Section 16.1.2

Exercise 16.9: What is a function template? What is a class template?

Exercise 16.10: What happens when a class template is instantiated?

Exercise 16.11: The following definition of List is incorrect. How would you fix it?

Click here to view code image

```
template <typename elemType> class ListItem;
template <typename elemType> class List {
public:
    List<elemType>();
    List<elemType>(const List<elemType> &);
    List<elemType>& operator=(const List<elemType> &);
    ~List();
    void insert(ListItem *ptr, elemType value);
private:
    ListItem *front, *end;
};
```

Exercise 16.12: Write your own version of the Blob and BlobPtr templates. including the various const members that were not shown in the text.

Exercise 16.13: Explain which kind of friendship you chose for the equality and relational operators for BlobPtr.

Exercise 16.14: Write a Screen class template that uses nontype parameters to define the height and width of the Screen.

Exercise 16.15: Implement input and output operators for your Screen template. Which, if any, friends are necessary in class Screen to make the input and output operators work? Explain why each friend declaration, if any, was needed.

Exercise 16.16: Rewrite the StrVec class (§ 13.5, p. 526) as a template named Vec.

16.1.3. Template Parameters

Like the names of function parameters, a template parameter name has no intrinsic

meaning. We ordinarily name type parameters T, but we can use any name:

Click here to view code image

```
template <typename Foo> Foo calc(const Foo& a, const Foo& b)
{
    Foo tmp = a; // tmp has the same type as the parameters and return type
    // ...
    return tmp; // return type and parameters have the same type
}
```

Template Parameters and Scope

Template parameters follow normal scoping rules. The name of a template parameter can be used after it has been declared and until the end of the template declaration or definition. As with any other name, a template parameter hides any declaration of that name in an outer scope. Unlike most other contexts, however, a name used as a template parameter may not be reused within the template:

Click here to view code image

```
typedef double A;
template <typename A, typename B> void f(A a, B b)
{
    A tmp = a; // tmp has same type as the template parameter A, not double
    double B; // error: redeclares template parameter B
}
```

Normal name hiding says that the typedef of A is hidden by the type parameter named A. Thus, tmp is not a double; it has whatever type gets bound to the template parameter A when calc is used. Because we cannot reuse names of template parameters, the declaration of the variable named B is an error.

Because a parameter name cannot be reused, the name of a template parameter can appear only once with in a given template parameter list:

Click here to view code image

```
// error: illegal reuse of template parameter name \,V\, template <typename \,V\,, typename \,V\,> // ...
```

Template Declarations

A template declaration must include the template parameters :

```
// declares but does not define compare and Blob
template <typename T> int compare(const T&, const T&);
template <typename T> class Blob;
```

As with function parameters, the names of a template parameter need not be the same across the declaration(s) and the definition of the same template:

Click here to view code image

```
// all three uses of calc refer to the same function template
template <typename T> T calc(const T&, const T&); // declaration
template <typename U> U calc(const U&, const U&); // declaration
// definition of the template
template <typename Type>
Type calc(const Type& a, const Type& b) { /* ... */ }
```

Of course, every declaration and the definition of a given template must have the same number and kind (i.e., type or nontype) of parameters.

Best Practices

For reasons we'll explain in § 16.3 (p. 698), declarations for all the templates needed by a given file usually should appear together at the beginning of a file before any code that uses those names.

Using Class Members That Are Types

Recall that we use the scope operator (::) to access both static members and type members (§ 7.4, p. 282, and § 7.6, p. 301). In ordinary (nontemplate) code, the compiler has access to the class defintion. As a result, it knows whether a name accessed through the scope operator is a type or a static member. For example, when we write string::size_type, the compiler has the definition of string and can see that size_type is a type.

Assuming T is a template type parameter, When the compiler sees code such as T::mem it won't know until instantiation time whether mem is a type or a static data member. However, in order to process the template, the compiler must know whether a name represents a type. For example, assuming T is the name of a type parameter, when the compiler sees a statement of the following form:

```
T::size type * p;
```

it needs to know whether we're defining a variable named p or are multiplying a static data member named size_type by a variable named p.

By default, the language assumes that a name accessed through the scope operator is not a type. As a result, if we want to use a type member of a template type parameter, we must explicitly tell the compiler that the name is a type. We do so by using the keyword typename:

```
template <typename T>
typename T::value_type top(const T& c)
{
    if (!c.empty())
        return c.back();
    else
        return typename T::value_type();
}
```

Our top function expects a container as its argument and uses typename to specify its return type and to generate a value initialized element (§ 7.5.3, p. 293) to return if c has no elements.

Note

When we want to inform the compiler that a name represents a type, we must use the keyword typename, not class.

Default Template Arguments

Just as we can supply default arguments to function parameters (§ 6.5.1, p. 236), we can also supply **default template arguments**. Under the new standard, we can supply default arguments for both function and class templates. Earlier versions of the language, allowed default arguments only with class templates.

As an example, we'll rewrite compare to use the library less function-object template (§ 14.8.2, p. 574) by default:

Click here to view code image

```
// compare has a default template argument, less<T>
// and a default function argument, F()
template <typename T, typename F = less<T>>
int compare(const T &v1, const T &v2, F f = F())
{
   if (f(v1, v2)) return -1;
   if (f(v2, v1)) return 1;
   return 0;
}
```

Here we've given our template a second type parameter, named F, that represents the type of a callable object (§ 10.3.2, p. 388) and defined a new function parameter, f, that will be bound to a callable object.

We've also provided defaults for this template parameter and its corresponding function parameter. The default template argument specifies that compare will use the library less function-object class, instantiated with the same type parameter as

compare. The default function argument says that f will be a default-initialized object of type F.

When users call this version of compare, they may supply their own comparison operation but are not required to do so:

Click here to view code image

```
bool i = compare(0, 42); // uses less; i is -1
// result depends on the isbns in item1 and item2
Sales_data item1(cin), item2(cin);
bool j = compare(item1, item2, compareIsbn);
```

The first call uses the default function argument, which is a default-initialized object of type less<T>. In this call, T is int so that object has type less<int>. This instantiation of compare will use less<int> to do its comparisons.

In the second call, we pass <code>compareIsbn</code> (§ 11.2.2, p. 425) and two objects of type <code>Sales_data</code>. When <code>compare</code> is called with three arguments, the type of the third argument must be a callable object that returns a type that is convertible to <code>bool</code> and takes arguments of a type compatible with the types of the first two arguments. As usual, the types of the template parameters are deduced from their corresponding function arguments. In this call, the type of <code>T</code> is deduced as <code>Sales_data</code> and <code>F</code> is deduced as the type of <code>compareIsbn</code>.

As with function default arguments, a template parameter may have a default argument only if all of the parameters to its right also have default arguments.

Template Default Arguments and Class Templates

Whenever we use a class template, we must always follow the template's name with brackets. The brackets indicate that a class must be instantiated from a template. In particular, if a class template provides default arguments for all of its template parameters, and we want to use those defaults, we must put an empty bracket pair following the template's name:

Click here to view code image

Here we instantiate two versions of Numbers: average_precision instantiates Numbers with T replaced by int; lots_of_precision instantiates Numbers with

T replaced by long double.

Exercises Section 16.1.3

Exercise 16.17: What, if any, are the differences between a type parameter that is declared as a typename and one that is declared as a class? When must typename be used?

Exercise 16.18: Explain each of the following function template declarations and identify whether any are illegal. Correct each error that you find.

Click here to view code image

- (a) template <typename T, U, typename V> void f1(T, U, V);
- (b) template <typename T> T f2(int &T);
- (c) inline template <typename T> T foo(T, unsigned int*);
- (d) template <typename T> f4(T, T);
- (e) typedef char Ctype; template <typename Ctype> Ctype f5(Ctype a);

Exercise 16.19: Write a function that takes a reference to a container and prints the elements in that container. Use the container's size_type and size members to control the loop that prints the elements.

Exercise 16.20: Rewrite the function from the previous exercise to use iterators returned from begin and end to control the loop.

16.1.4. Member Templates

A class—either an ordinary class or a class template—may have a member function that is itself a template. Such members are referred to as **member templates**. Member templates may not be virtual.

Member Templates of Ordianary (Nontemplate) Classes

As an example of an ordinary class that has a member template, we'll define a class that is similar to the default deleter type used by unique_ptr (§ 12.1.5, p. 471). Like the default deleter, our class will have an overloaded function-call operator (§ 14.8, p. 571) that will take a pointer and execute delete on the given pointer. Unlike the default deleter, our class will also print a message whenever the deleter is executed. Because we want to use our deleter with any type, we'll make the call operator a template:

Click here to view code image

// function-object class that calls delete on a given pointer

Like any other template, a member template starts with its own template parameter list. Each <code>DebugDelete</code> object has an <code>ostream</code> member on which to write, and a member function that is itself a template. We can use this class as a replacement for <code>delete</code>:

Click here to view code image

```
double* p = new double;
DebugDelete d;  // an object that can act like a delete expression
d(p); // calls DebugDelete::operator()(double*), which deletes p
int* ip = new int;
// calls operator()(int*) on a temporary DebugDelete object
DebugDelete()(ip);
```

Because calling a DebugDelete object deletes its given pointer, we can also use DebugDelete as the deleter of a unique_ptr. To override the deleter of a unique_ptr, we supply the type of the deleter inside brackets and supply an object of the deleter type to the constructor (§ 12.1.5, p. 471):

Click here to view code image

```
// destroying the the object to which p points
// instantiates DebugDelete::operator()<int>(int*)
unique_ptr<int, DebugDelete> p(new int, DebugDelete());
// destroying the the object to which sp points
// instantiates DebugDelete::operator()<string>(string*)
unique_ptr<string, DebugDelete> sp(new string, DebugDelete());
```

Here, we've said that p's deleter will have type DebugDelete, and we have supplied an unnamed object of that type in p's constructor.

The unique_ptr destructor calls the DebugDelete's call operator. Thus, whenever unique_ptr's destructor is instantiated, DebugDelete's call operator will also be instantiated: Thus, the definitions above will instantiate:

```
// sample instantiations for member templates of DebugDelete
void DebugDelete::operator()(int *p) const { delete p; }
void DebugDelete::operator()(string *p) const { delete p; }
```

Member Templates of Class Templates

We can also define a member template of a class template. In this case, both the class and the member have their own, independent, template parameters.

As an example, we'll give our Blob class a constructor that will take two iterators denoting a range of elements to copy. Because we'd like to support iterators into varying kinds of sequences, we'll make this constructor a template:

Click here to view code image

```
template <typename T> class Blob {
   template <typename It> Blob(It b, It e);
   // ...
};
```

This constructor has its own template type parameter, It, which it uses for the type of its two function parameters.

Unlike ordinary function members of class templates, member templates *are* function templates. When we define a member template outside the body of a class template, we must provide the template parameter list for the class template and for the function template. The parameter list for the class template comes first, followed by the member's own template parameter list:

Click here to view code image

Here we are defining a member of a class template that has one template type parameter, which we have named \mathtt{T} . The member itself is a function template that has a type parameter named \mathtt{It} .

Instantiation and Member Templates

To instantiate a member template of a class template, we must supply arguments for the template parameters for both the class and the function templates. As usual, argument(s) for the class template parameter(s) are determined by the type of the object through which we call the member template. Also as usual, the compiler typically deduces template argument(s) for the member template's own parameter(s) from the arguments passed in the call (§ 16.1.1, p. 653):

```
int ia[] = \{0,1,2,3,4,5,6,7,8,9\};
```

```
vector<long> vi = {0,1,2,3,4,5,6,7,8,9};
list<const char*> w = {"now", "is", "the", "time"};
// instantiates the Blob<int> class
// and the Blob<int> constructor that has two int* parameters
Blob<int> al(begin(ia), end(ia));
// instantiates the Blob<int> constructor that has
// two vector<long>::iterator parameters
Blob<int> a2(vi.begin(), vi.end());
// instantiates the Blob<string> class and the Blob<string>
// constructor that has two (list<const char*>::iterator parameters
Blob<string> a3(w.begin(), w.end());
```

When we define a1, we explicitly specify that the compiler should instantiate a version of Blob with the template parameter bound to int. The type parameter for the constructor's own parameters will be deduced from the type of begin(ia) and end(ia). That type is int*. Thus, the definition of a1 instantiates:

```
Blob<int>::Blob(int*, int*);
```

The definition of a2 uses the already instantiated Blob<int> class, and instantiates the constructor with It replaced by vector<short>::iterator. The definition of a3 (explicitly) instantiates the Blob with its template parameter bound to string and (implicitly) instantiates the member template constructor of that class with its parameter bound to list<const char*>.

Exercises Section 16.1.4

Exercise 16.21: Write your own version of DebugDelete.

Exercise 16.22: Revise your TextQuery programs from § 12.3 (p. 484) so that the shared_ptr members use a DebugDelete as their deleter (§ 12.1.4, p. 468).

Exercise 16.23: Predict when the call operator will be executed in your main query program. If your expectations and what happens differ, be sure you understand why.

Exercise 16.24: Add a constructor that takes two iterators to your Blob template.

16.1.5. Controlling Instantiations

The fact that instantiations are generated when a template is used (§ 16.1.1, p. 656) means that the same instantiation may appear in multiple object files. When two or more separately compiled source files use the same template with the same template arguments, there is an instantiation of that template in each of those files.

In large systems, the overhead of instantiating the same template in multiple files can become significant. Under the new standard, we can avoid this overhead through an **explicit instantiation**. An explicit instantiation has the form

Click here to view code image

```
extern template declaration; // instantiation declaration template declaration; // instantiation definition
```

where *declaration* is a class or function declaration in which all the template parameters are replaced by the template arguments. For example,

Click here to view code image

When the compiler sees an extern template declaration, it will not generate code for that instantiation in that file. Declaring an instantiation as extern is a promise that there will be a nonextern use of that instantiation elsewhere in the program. There may be several extern declarations for a given instantiation but there must be exactly one definition for that instantiation.

Because the compiler automatically instantiates a template when we use it, the extern declaration must appear before any code that uses that instantiation:

Click here to view code image

```
// Application.cc
// these template types must be instantiated elsewhere in the program
extern template class Blob<string>;
extern template int compare(const int&, const int&);
Blob<string> sa1, sa2; // instantiation will appear elsewhere
// Blob<int> and its initializer_list constructor instantiated in this file
Blob<int> a1 = {0,1,2,3,4,5,6,7,8,9};
Blob<int> a2(a1); // copy constructor instantiated in this file
int i = compare(a1[0], a2[0]); // instantiation will appear elsewhere
```

The file Application.o will contain instantiations for Blob<int>, along with the initializer_list and copy constructors for that class. The compare<int> function and Blob<string> class will not be instantiated in that file. There must be definitions of these templates in some other file in the program:

```
// templateBuild.cc
// instantiation file must provide a (nonextern) definition for every
// type and function that other files declare as extern
```

template int compare(const int&, const int&); template class Blob<string>; // instantiates all members of the class template

When the compiler sees an instantiation definition (as opposed to a declaration), it generates code. Thus, the file templateBuild.o will contain the definitions for compare instantiated with int and for the Blob<string> class. When we build the application, we must link templateBuild.o with the Application.o files.

Warning

There must be an explicit instantiation definition somewhere in the program for every instantiation declaration.

Instantiation Definitions Instantiate All Members

An instantiation definition for a class template instantiates all the members of that template including inline member functions. When the compiler sees an instantiation definition it cannot know which member functions the program uses. Hence, unlike the way it handles ordinary class template instantiations, the compiler instantiates all the members of that class. Even if we do not use a member, that member will be instantiated. Consequently, we can use explicit instantiation only for types that can be used with all the members of that template.

An instantiation definition can be used only for types that can be used with every member function of a class template.

16.1.6. Efficiency and Flexibility

The library smart pointer types (§ 12.1, p. 450) offer a good illustration of design choices faced by designers of templates.

The obvious difference between shared_ptr and unique_ptr is the strategy they use in managing the pointer they hold—one class gives us shared ownership; the other owns the pointer that it holds. This difference is essential to what these classes do.

These classes also differ in how they let users override their default deleter. We can easily override the deleter of a shared ptr by passing a callable object when we

create or reset the pointer. In contrast, the type of the deleter is part of the type of a unique_ptr object. Users must supply that type as an explicit template argument when they define a unique_ptr. As a result, it is more complicated for users of unique_ptr to provide their own deleter.

Exercises Section 16.1.5

Exercise 16.25: Explain the meaning of these declarations:

Click here to view code image

```
extern template class vector<string>;
template class vector<Sales_data>;
```

Exercise 16.26: Assuming NoDefault is a class that does not have a default constructor, can we explicitly instantiate vector<NoDefault>? If not, why not?

Exercise 16.27: For each labeled statement explain what, if any, instantiations happen. If a template is instantiated, explain why; if not, explain why not.

Click here to view code image

```
template <typename T> class Stack { };
void f1(Stack<char>);
                                          //(a)
class Exercise {
    Stack<double> &rsd;
                                          //(b)
    Stack<int> si;
                                          //(c)
};
int main() {
    Stack<char> *sc;
                                          //(d)
    f1(*sc);
                                          // (e)
    int iObj = sizeof(Stack< string >); // (f)
}
```

The difference in how the deleter is handled is incidental to the functionality of these classes. However, as we'll see, this difference in implementation strategy may have important performance impacts.

Binding the Deleter at Run Time

Although we don't know how the library types are implemented, we can infer that shared_ptr must access its deleter indirectly. That is the deleter must be stored as a pointer or as a class (such as function (§ 14.8.3, p. 577)) that encapsulates a pointer.

We can be certain that shared_ptr does not hold the deleter as a direct member,

because the type of the deleter isn't known until run time. Indeed, we can change the type of the deleter in a given <code>shared_ptr</code> during that <code>shared_ptr</code>'s lifetime. We can construct a <code>shared_ptr</code> using a deleter of one type, and subsequently use <code>reset</code> to give that same <code>shared_ptr</code> a different type of deleter. In general, we cannot have a member whose type changes at run time. Hence, the deleter must be stored indirectly.

To think about how the deleter must work, let's assume that shared_ptr stores the pointer it manages in a member named p, and that the deleter is accessed through a member named del. The shared_ptr destructor must include a statement such as

Click here to view code image

```
// value of del known only at run time; call through a pointer
del ? del(p) : delete p; // del(p) requires run-time jump to del's location
```

Because the deleter is stored indirectly, the call del(p) requires a run-time jump to the location stored in del to execute the code to which del points.

Binding the Deleter at Compile Time

Now, let's think about how unique_ptr might work. In this class, the type of the deleter is part of the type of the unique_ptr. That is, unique_ptr has two template parameters, one that represents the pointer that the unique_ptr manages and the other that represents the type of the deleter. Because the type of the deleter is part of the type of a unique_ptr, the type of the deleter member is known at compile time. The deleter can be stored directly in each unique_ptr object.

The unique_ptr destructor operates similarly to its shared_ptr counterpart in that it calls a user-supplied deleter or executes delete on its stored pointer:

Click here to view code image

```
// del bound at compile time; direct call to the deleter is instantiated
del(p); // no run-time overhead
```

The type of del is either the default deleter type or a user-supplied type. It doesn't matter; either way the code that will be executed is known at compile time. Indeed, if the deleter is something like our DebugDelete class (§ 16.1.4, p. 672) this call might even be inlined at compile time.

By binding the deleter at compile time, unique_ptr avoids the run-time cost of an indirect call to its deleter. By binding the deleter at run time, shared_ptr makes it easier for users to override the deleter.

Exercises Section 16.1.6

Exercise 16.28: Write your own versions of shared_ptr and

unique_ptr.

Exercise 16.29: Revise your Blob class to use your version of shared_ptr rather than the library version.

Exercise 16.30: Rerun some of your programs to verify your shared_ptr and revised Blob classes. (Note: Implementing the weak_ptr type is beyond the scope of this Primer, so you will not be able to use the BlobPtr class with your revised Blob.)

Exercise 16.31: Explain how the compiler might inline the call to the deleter if we used DebugDelete with unique_ptr.

16.2. Template Argument Deduction

We've seen that, by default, the compiler uses the arguments in a call to determine the template parameters for a function template. The process of determining the template arguments from the function arguments is known as template argument deduction. During template argument deduction, the compiler uses types of the arguments in the call to find the template arguments that generate a version of the function that best matches the given call.

16.2.1. Conversions and Template Type Parameters

As with a nontemplate function, the arguments we pass in a call to a function template are used to initialize that function's parameters. Function parameters whose type uses a template type parameter have special initialization rules. Only a very limited number of conversions are automatically applied to such arguments. Rather than converting the arguments, the compiler generates a new instantiation.

As usual, top-level consts (§ 2.4.3, p. 63) in either the parameter or the argument are ignored. The only other conversions performed in a call to a function template are

- const conversions: A function parameter that is a reference (or pointer) to a const can be passed a reference (or pointer) to a nonconst object (§ 4.11.2, p. 162).
- Array- or function-to-pointer conversions: If the function parameter is not a reference type, then the normal pointer conversion will be applied to arguments of array or function type. An array argument will be converted to a pointer to its first element. Similarly, a function argument will be converted to a pointer to the function's type (§ 4.11.2, p. 161).

Other conversions, such as the arithmetic conversions (§ 4.11.1, p. 159), derived-to-base (§ 15.2.2, p. 597), and user-defined conversions (§ 7.5.4, p. 294, and § 14.9, p. 579), are not performed.

As examples, consider calls to the functions fobj and fref. The fobj function copies its parameters, whereas fref's parameters are references:

Click here to view code image

```
template <typename T> T fobj(T, T); // arguments are copied
template <typename T> T fref(const T&, const T&); // references
string s1("a value");
const string s2("another value");
fobj(s1, s2); // calls fobj(string, string); const is ignored
fref(s1, s2); // calls fref(const string&, const string&)
                 // uses premissible conversion to const on s1
int a[10], b[42];
fobj(a, b); // calls f(int*, int*)
fref(a, b); // error: array types don't match
```

In the first pair of calls, we pass a string and a const string. Even though these types do not match exactly, both calls are legal. In the call to fobj, the arguments are copied, so whether the original object is const doesn't matter. In the call to fref, the parameter type is a reference to const. Conversion to const for a reference parameter is a permitted conversion, so this call is legal.

In the next pair of calls, we pass array arguments in which the arrays are different sizes and hence have different types. In the call to fobj, the fact that the array types differ doesn't matter. Both arrays are converted to pointers. The template parameter type in fobj is int*. The call to fref, however, is illegal. When the parameter is a reference, the arrays are not converted to pointers (§ 6.2.4, p. 217). The types of a and b don't match, so the call is in error.

const conversions and array or function to pointer are the only automatic conversions for arguments to parameters with template types.

Function Parameters That Use the Same Template Parameter Type

A template type parameter can be used as the type of more than one function parameter. Because there are limited conversions, the arguments to such parameters must have essentially the same type. If the deduced types do not match, then the call is an error. For example, our compare function (§ 16.1.1, p. 652) takes two const T& parameters. Its arguments must have essentially the same type:

```
long lng;
```

```
compare(lng, 1024); // error: cannot instantiate compare(long, int)
```

This call is in error because the arguments to compare don't have the same type. The template argument deduced from the first argument is long; the one for the second is int. These types don't match, so template argument deduction fails.

If we want to allow normal conversions on the arguments, we can define the function with two type parameters:

Click here to view code image

```
// argument types can differ but must be compatible
template <typename A, typename B>
int flexibleCompare(const A& v1, const B& v2)
{
   if (v1 < v2) return -1;
   if (v2 < v1) return 1;
   return 0;
}</pre>
```

Now the user may supply arguments of different types:

Click here to view code image

```
long lng;
flexibleCompare(lng, 1024); // ok: calls flexibleCompare(long, int)
```

Of course, a < operator must exist that can compare values of those types.

Normal Conversions Apply for Ordinary Arguments

A function template can have parameters that are defined using ordinary types—that is, types that do not involve a template type parameter. Such arguments have no special processing; they are converted as usual to the corresponding type of the parameter (§ 6.1, p. 203). For example, consider the following template:

Click here to view code image

```
template <typename T> ostream &print(ostream &os, const T
&obj)
{
    return os << obj;
}</pre>
```

The first function parameter has a known type, ostream&. The second parameter, obj, has a template parameter type. Because the type of os is fixed, normal conversions are applied to arguments passed to os when print is called:

```
print(cout, 42); // instantiates print(ostream&, int)
ofstream f("output");
print(f, 10); // uses print(ostream&, int); converts f to ostream&
```

In the first call, the type of the first argument exactly matches the type of the first parameter. This call will cause a version of print that takes an ostream& and an int to be instantiated. In the second call, the first argument is an ofstream and there is a conversion from ofstream to ostream& (§ 8.2.1, p. 317). Because the type of this parameter does not depend on a template parameter, the compiler will implicitly convert f to ostream&.

Note

Normal conversions are applied to arguments whose type is not a template parameter.

Exercises Section 16.2.1

Exercise 16.32: What happens during template argument deduction?

Exercise 16.33: Name two type conversions allowed on function arguments involved in template argument deduction.

Exercise 16.34: Given only the following code, explain whether each of these calls is legal. If so, what is the type of T? If not, why not?

Click here to view code image

```
template <class T> int compare(const T&, const T&);
(a) compare("hi", "world");
(b) compare("bye", "dad");
```

Exercise 16.35: Which, if any, of the following calls are errors? If the call is legal, what is the type of T? If the call is not legal, what is the problem?

Click here to view code image

```
template <typename T> T calc(T, int);
template <typename T> T fcn(T, T);
double d; float f; char c;

(a) calc(c, 'c');
(b) calc(d, f);
(c) fcn(c, 'c');
(d) fcn(d, f);
```

Exercise 16.36: What happens in the following calls:

```
template <typename T> f1(T, T);
template <typename T1, typename T2) f2(T1, T2);</pre>
```

```
int i = 0, j = 42, *p1 = &i, *p2 = &j;
const int *cp1 = &i, *cp2 = &j;

(a) f1(p1, p2);
(b) f2(p1, p2);
(c) f1(cp1, cp2);
(d) f2(cp1, cp2);
(e) f1(p1, cp1);
(f) f2(p1, cp1);
```

16.2.2. Function-Template Explicit Arguments

In some situations, it is not possible for the compiler to deduce the types of the template arguments. In others, we want to allow the user to control the template instantiation. Both cases arise most often when a function return type differs from any of those used in the parameter list.

Specifying an Explicit Template Argument

As an example in which we want to let the user specify which type to use, we'll define a function template named sum that takes arguments of two different types. We'd like to let the user specify the type of the result. That way the user can choose whatever precision is appropriate.

We can let the user control the type of the return by defining a third template parameter to represent the return type:

Click here to view code image

```
// T1 cannot be deduced: it doesn't appear in the function parameter list
template <typename T1, typename T2, typename T3>
T1 sum(T2, T3);
```

In this case, there is no argument whose type can be used to deduce the type of T1. The caller must provide an **explicit template argument** for this parameter on each call to sum.

We supply an explicit template argument to a call the same way that we define an instance of a class template. Explicit template arguments are specified inside angle brackets after the function name and before the argument list:

Click here to view code image

// T1 is explicitly specified; T2 and T3 are inferred from the argument types

```
auto val3 = sum<long long>(i, lng); // long long sum(int, long)
```

This call explicitly specifies the type for T1. The compiler will deduce the types for T2 and T3 from the types of i and lng.

Explicit template argument(s) are matched to corresponding template parameter(s) from left to right; the first template argument is matched to the first template parameter, the second argument to the second parameter, and so on. An explicit template argument may be omitted only for the trailing (right-most) parameters, and then only if these can be deduced from the function parameters. If our sum function had been written as

Click here to view code image

```
// poor design: users must explicitly specify all three template parameters
template <typename T1, typename T2, typename T3>
T3 alternative_sum(T2, T1);
```

then we would always have to specify arguments for all three parameters:

Click here to view code image

```
// error: can't infer initial template parameters
auto val3 = alternative_sum<long long>(i, lng);
// ok: all three parameters are explicitly specified
auto val2 = alternative_sum<long long, int, long>(i, lng);
```

Normal Conversions Apply for Explicitly Specified Arguments

For the same reasons that normal conversions are permitted for parameters that are defined using ordinary types (§ 16.2.1, p. 680), normal conversions also apply for arguments whose template type parameter is explicitly specified:

Click here to view code image

```
long lng;
compare(lng, 1024);  // error: template parameters don't match
compare<long>(lng, 1024);  // ok: instantiates compare(long, long)
compare<int>(lng, 1024);  // ok: instantiates compare(int, int)
```

As we've seen, the first call is in error because the arguments to compare must have the same type. If we explicitly specify the template parameter type, normal conversions apply. Thus, the call to compare<long> is equivalent to calling a function taking two const long& parameters. The int parameter is automatically converted to long. In the second call, T is explicitly specified as int, so lng is converted to int.

Exercises Section 16.2.2

Exercise 16.37: The library max function has two function parameters and

returns the larger of its arguments. This function has one template type parameter. Could you call max passing it an int and a double? If so, how? If not, why not?

Exercise 16.38: When we call make_shared (§ 12.1.1, p. 451), we have to provide an explicit template argument. Explain why that argument is needed and how it is used.

Exercise 16.39: Use an explicit template argument to make it sensible to pass two string literals to the original version of compare from § 16.1.1 (p. 652).

16.2.3. Trailing Return Types and Type Transformation

Using an explicit template argument to represent a template function's return type works well when we want to let the user determine the return type. In other cases, requiring an explicit template argument imposes a burden on the user with no compensating advantage. For example, we might want to write a function that takes a pair of iterators denoting a sequence and returns a reference to an element in the sequence:

Click here to view code image

```
template <typename It>
??? &fcn(It beg, It end)
{
    // process the range
    return *beg; // return a reference to an element from the range
}
```

We don't know the exact type we want to return, but we do know that we want that type to be a reference to the element type of the sequence we're processing:

Click here to view code image

```
vector<int> vi = {1,2,3,4,5};
Blob<string> ca = { "hi", "bye" };
auto &i = fcn(vi.begin(), vi.end()); // fcn should return int&
auto &s = fcn(ca.begin(), ca.end()); // fcn should return string&
```

Here, we know that our function will return *beg, and we know that we can use decltype(*beg) to obtain the type of that expression. However, beg doesn't exist until the parameter list has been seen. To define this function, we must use a trailing return type (§ 6.3.3, p. 229). Because a trailing return appears after the parameter list, it can use the function's parameters:

Click here to view code image

```
// a trailing return lets us declare the return type after the parameter list is seen
template <typename It>
auto fcn(It beg, It end) -> decltype(*beg)
{
    // process the range
    return *beg; // return a reference to an element from the range
}
```

Here we've told the compiler that fcn's return type is the same as the type returned by dereferencing its beg parameter. The dereference operator returns an Ivalue (§ 4.1.1, p. 136), so the type deduced by decltype is a reference to the type of the element that beg denotes. Thus, if fcn is called on a sequence of strings, the return type will be string&. If the sequence is int, the return will be int&.

The Type Transformation Library Template Classes

Sometimes we do not have direct access to the type that we need. For example, we might want to write a function similar to fcn that returns an element by value (§ 6.3.2, p. 224), rather than a reference to an element.

The problem we face in writing this function is that we know almost nothing about the types we're passed. In this function, the only operations we know we can use are iterator operations, and there are no iterator operations that yield elements (as opposed to references to elements).

To obtain the element type, we can use a library **type transformation** template. These templates are defined in the **type_traits** header. In general the classes in type_traits are used for so-called template metaprogramming, a topic that is beyond the scope of this Primer. However, the type transformation templates are useful in ordinary programming as well. These templates are described in Table 16.1 and we'll see how they are implemented in § 16.5 (p. 710).

Table 16.1. Standard Type Transformation Templates

For Mod <t>, where Mod is</t>	If T is	Then Mod <t>::type is</t>
remove reference	X& or X&&	Х
e zne nas al eska pokazek	otherwise	T
add_const	X&, const X, or function	T
	otherwise	const T
add_lvalue_reference	X&	T
	X&&	X&
	otherwise	T&
add_rvalue_reference	X& or X&&	T
**************************************	otherwise	T&&
remove_pointer	X*	X
RECA	otherwise	T
add_pointer	X& or X&&	X*
(TO) (1)	otherwise	T*
make signed	unsigned X	X
	otherwise	T
make unsigned	signed type	unsigned T
8 AND THE TOTAL TO	otherwise	T
remove_extent	X[n]	X
	otherwise	T
remove_all_extents	X[n1][n2]	X
= =	otherwise	$^{10}\mathbf{T}$

In this case, we can use remove_reference to obtain the element type. The remove_reference template has one template type parameter and a (public) type member named type. If we instantiate remove_reference with a reference type, then type will be the referred-to type. For example, if we instantiate remove_reference<int&>, the type member will be int. Similarly, if we instantiate remove_reference<string&>, type will be string, and so on. More generally, given that beg is an iterator:

Click here to view code image

remove_reference<decltype(*beg)>::type

will be the type of the element to which beg refers: decltype(*beg) returns the reference type of the element type. remove_reference::type strips off the reference, leaving the element type itself.

Using remove_reference and a trailing return with decltype, we can write our function to return a copy of an element's value:

```
// must use typename to use a type member of a template parameter; see § 16.1.3 (p.
670)
template <typename It>
```

```
auto fcn2(It beg, It end) ->
          typename remove_reference<decltype(*beg)>::type
{
          // process the range
          return *beg; // return a copy of an element from the range
}
```

Note that type is member of a class that depends on a template parameter. As a result, we must use typename in the declaration of the return type to tell the compiler that type represents a type (§ 16.1.3, p. 670).

Each of the type transformation templates described in Table 16.1 works similarly to remove_reference. Each template has a public member named type that represents a type. That type may be related to the template's own template type parameter in a way that is indicated by the template's name. If it is not possible (or not necessary) to transform the template's parameter, the type member is the template parameter type itself. For example, if T is a pointer type, then remove_pointer<T>::type is the type to which T points. If T isn't a pointer, then no transformation is needed. In this case, type is the same type as T.

Exercises Section 16.2.3

Exercise 16.40: Is the following function legal? If not, why not? If it is legal, what, if any, are the restrictions on the argument type(s) that can be passed, and what is the return type?

Click here to view code image

```
template <typename It>
auto fcn3(It beg, It end) -> decltype(*beg + 0)
{
    // process the range
    return *beg; // return a copy of an element from the range
}
```

Exercise 16.41: Write a version of sum with a return type that is guaranteed to be large enough to hold the result of the addition.

16.2.4. Function Pointers and Argument Deduction

When we initialize or assign a function pointer (§ 6.7, p. 247) from a function template, the compiler uses the type of the pointer to deduce the template argument(s).

As an example, assume we have a function pointer that points to a function returning an int that takes two parameters, each of which is a reference to a const

int. We can use that pointer to point to an instantiation of compare:

Click here to view code image

```
template <typename T> int compare(const T&, const T&);
// pfl points to the instantiation int compare(const int&, const int&)
int (*pfl)(const int&, const int&) = compare;
```

The type of the parameters in pf1 determines the type of the template argument for T. The template argument for T is int. The pointer pf1 points to the instantiation of compare with T bound to int. It is an error if the template arguments cannot be determined from the function pointer type:

Click here to view code image

```
// overloaded versions of func; each takes a different function pointer type
void func(int(*)(const string&, const string&));
void func(int(*)(const int&, const int&));
func(compare); // error: which instantiation of compare?
```

The problem is that by looking at the type of func's parameter, it is not possible to determine a unique type for the template argument. The call to func could instantiate the version of compare that takes ints or the version that takes strings. Because it is not possible to identify a unique instantiation for the argument to func, this call won't compile.

We can disambiguate the call to func by using explicit template arguments:

Click here to view code image

```
// ok: explicitly specify which version of compare to instantiate
func(compare<int>); // passing compare(const int&, const int&)
```

This expression calls the version of func that takes a function pointer with two const int& parameters.

Note

When the address of a function-template instantiation is taken, the context must be such that it allows a unique type or value to be determined for each template parameter.

16.2.5. Template Argument Deduction and References

In order to understand type deduction from a call to a function such as

```
template <typename T> void f(T &p);
```

in which the function's parameter p is a reference to a template type parameter T, it is important to keep in mind two points: Normal reference binding rules apply; and consts are low level, not top level.

Type Deduction from Lvalue Reference Function Parameters

When a function parameter is an ordinary (Ivalue) reference to a template type parameter (i.e., that has the form T&), the binding rules say that we can pass only an Ivalue (e.g., a variable or an expression that returns a reference type). That argument might or might not have a const type. If the argument is const, then T will be deduced as a const type:

Click here to view code image

```
template <typename T> void f1(T&); // argument must be an lvalue // calls to f1 use the referred-to type of the argument as the template parameter type f1(i); // i is an int; template parameter T is int f1(ci); // ci is a const int; template parameter T is const int f1(5); // error: argument to a & parameter must be an lvalue
```

If a function parameter has type const T&, normal binding rules say that we can pass any kind of argument—an object (const or otherwise), a temporary, or a literal value. When the function parameter is itself const, the type deduced for T will not be a const type. The const is already part of the function parameter type; therefore, it does not also become part of the template parameter type:

Click here to view code image

```
template <typename T> void f2(const T&); // can take an rvalue // parameter in f2 is const &; const in the argument is irrelevant // in each of these three calls, f2's function parameter is inferred as const int& f2(i); // i is an int; template parameter T is int f2(ci); // ci is a const int, but template parameter T is int f2(5); // a const & parameter can be bound to an rvalue; T is int
```

Type Deduction from Rvalue Reference Function Parameters

When a function parameter is an rvalue reference (§ 13.6.1, p. 532) (i.e., has the form T&&), normal binding rules say that we can pass an rvalue to this parameter. When we do so, type deduction behaves similarly to deduction for an ordinary Ivalue reference function parameter. The deduced type for T is the type of the rvalue:

```
template <typename T> void f3(T&&);
```

f3(42); // argument is an rvalue of type int; template parameter T is int

Reference Collapsing and Rvalue Reference Parameters

Assuming i is an int object, we might think that a call such as f3(i) would be illegal. After all, i is an Ivalue, and normally we cannot bind an rvalue reference to an Ivalue. However, the language defines two exceptions to normal binding rules that allow this kind of usage. These exceptions are the foundation for how library facilities such as move operate.

The first exception affects how type deduction is done for rvalue reference parameters. When we pass an Ivalue (e.g., i) to a function parameter that is an rvalue reference to a template type parameter (e.g., T&&), the compiler deduces the template type parameter as the argument's Ivalue reference type. So, when we call f3(i), the compiler deduces the type of T as int&, not int.

Deducing T as int& would seem to mean that f3's function parameter would be an rvalue reference to the type int&. Ordinarily, we cannot (directly) define a reference to a reference (§ 2.3.1, p. 51). However, it is possible to do so indirectly through a type alias (§ 2.5.1, p. 67) or through a template type parameter.

In such contexts, we see the second exception to the normal binding rules: If we indirectly create a reference to a reference, then those references "collapse." In all but one case, the references collapse to form an ordinary Ivalue reference type. The new standard, expanded the collapsing rules to include rvalue references. References collapse to form an rvalue reference only in the specific case of an rvalue reference to an rvalue reference. That is, for a given type x:

- X& &, X& &&, and X&& & all collapse to type X&
- The type x&& && collapses to x&&

Reference collapsing applies only when a reference to a reference is created indirectly, such as in a type alias or a template parameter.

The combination of the reference collapsing rule and the special rule for type deduction for rvalue reference parameters means that we can call £3 on an Ivalue. When we pass an Ivalue to £3's (rvalue reference) function parameter, the compiler will deduce T as an Ivalue reference type:

```
f3(i); // argument is an lvalue; template parameter T is int&
f3(ci); // argument is an lvalue; template parameter T is const int&
```

When a template parameter T is deduced as a reference type, the collapsing rule says that the function parameter T&& collapses to an Ivalue reference type. For example, the resulting instantiation for f3(i) would be something like

Click here to view code image

```
// invalid code, for illustration purposes only
void f3<int&>(int& &&); // when T is int&, function parameter is int& &&
```

The function parameter in f3 is T&& and T is int&, so T&& is int& &&, which collapses to int&. Thus, even though the form of the function parameter in £3 is an rvalue reference (i.e., T&&), this call instantiates £3 with an Ivalue reference type (i.e., int&):

Click here to view code image

```
void f3<int\&>(int\&); // when T is int\&, function parameter collapses to
int&
```

There are two important consequences from these rules:

- A function parameter that is an rvalue reference to a template type parameter (e.g., T&&) can be bound to an Ivalue; and
- If the argument is an Ivalue, then the deduced template argument type will be an Ivalue reference type and the function parameter will be instantiated as an (ordinary) Ivalue reference parameter (T&)

It is also worth noting that by implication, we can pass any type of argument to a **T&& function parameter**. A parameter of such a type can (obviously) be used with rvalues, and as we've just seen, can be used by Ivalues as well.

An argument of any type can be passed to a function parameter that is an rvalue reference to a template parameter type (i.e., T&&). When an Ivalue is passed to such a parameter, the function parameter is instantiated as an ordinary, Ivalue reference (T&).

Writing Template Functions with Rvalue Reference Parameters

The fact that the template parameter can be deduced to a reference type can have surprising impacts on the code inside the template:

```
template <typename T> void f3(T&& val)
```

```
T t = val; // copy or binding a reference?
t = fcn(t); // does the assignment change only t or val and t?
if (val == t) { /* ... */ } // always true if T is a reference type
}
```

When we call f3 on an rvalue, such as the literal 42, T is int. In this case, the local variable t has type int and is initialized by copying the value of the parameter val. When we assign to t, the parameter val remains unchanged.

On the other hand, when we call f3 on the lvalue i, then T is int&. When we define and initialize the local variable t, that variable has type int&. The initialization of t binds t to val. When we assign to t, we change val at the same time. In this instantiation of f3, the if test will always yield true.

It is surprisingly hard to write code that is correct when the types involved might be plain (nonreference) types or reference types (although the type transformation classes such as remove_reference can help (§ 16.2.3, p. 684)).

In practice, rvalue reference parameters are used in one of two contexts: Either the template is forwarding its arguments, or the template is overloaded. We'll look at forwarding in § 16.2.7 (p. 692) and at template overloading in § 16.3 (p. 694).

For now, it's worth noting that function templates that use rvalue references often use overloading in the same way as we saw in § 13.6.3 (p. 544):

Click here to view code image

As with nontemplate functions, the first version will bind to modifiable rvalues and the second to lvalues or to const rvalues.

Exercises Section 16.2.5

Exercise 16.42: Determine the type of T and of val in each of the following calls:

Click here to view code image

```
template <typename T> void g(T&& val);
int i = 0; const int ci = i;
(a) g(i);
(b) g(ci);
(c) q(i * ci);
```

Exercise 16.43: Using the function defined in the previous exercise, what

would the template parameter of g be if we called g(i = ci)?

Exercise 16.44: Using the same three calls as in the first exercise, determine the types for T if g's function parameter is declared as T (not T&&). What if g's function parameter is const T&?

Exercise 16.45: Given the following template, explain what happens if we call g on a literal value such as 42. What if we call g on a variable of type int?

Click here to view code image

```
template <typename T> void g(T&& val) { vector<T> v; }
```

16.2.6. Understanding std::move

The library move function (§ 13.6.1, p. 533) is a good illustration of a template that uses rvalue references. Fortunately, we can use move without understanding the template mechanisms that it uses. However, looking at how move works can help cement our general understanding, and use, of templates.

In § 13.6.2 (p. 534) we noted that although we cannot directly bind an rvalue reference to an Ivalue, we can use move to obtain an rvalue reference bound to an Ivalue. Because move can take arguments of essentially any type, it should not be surprising that move is a function template.

How std::move Is Defined

The standard defines move as follows:

Click here to view code image

This code is short but subtle. First, move's function parameter, T&&, is an rvalue reference to a template parameter type. Through reference collapsing, this parameter can match arguments of any type. In particular, we can pass either an Ivalue or an rvalue to move:

Click here to view code image

```
string s1("hi!"), s2;
s2 = std::move(string("bye!")); // ok: moving from an rvalue
s2 = std::move(s1); // ok: but after the assignment s1 has indeterminate
value
```

How std::move Works

In the first assignment, the argument to move is the rvalue result of the string constructor, string("bye"). As we've seen, when we pass an rvalue to an rvalue reference function parameter, the type deduced from that argument is the referred-to type (§ 16.2.5, p. 687). Thus, in std::move(string("bye!")):

- The deduced type of T is string.
- Therefore, remove_reference is instantiated with string.
- The type member of remove_reference<string> is string.
- The return type of move is string&&.
- move's function parameter, t, has type string&&.

Accordingly, this call instantiates move<string>, which is the function

string&& move(string &&t)

The body of this function returns $static_cast < string&&>(t)$. The type of t is already string&&, so the cast does nothing. Therefore, the result of this call is the rvalue reference it was given.

Now consider the second assignment, which calls std:move(s1). In this call, the argument to move is an Ivalue. This time:

- The deduced type of T is string& (reference to string, not plain string).
- Therefore, remove_reference is instantiated with string&.
- The type member of remove_reference<string&> is string,
- The return type of move is still string&&.
- move's function parameter, t, instantiates as string& &&, which collapses to string&.

Thus, this call instantiates move<string&>, which is

string&& move(string &t)

and which is exactly what we're after—we want to bind an rvalue reference to an lvalue. The body of this instantiation returns static_cast<string&&>(t). In this case, the type of t is string&, which the cast converts to string&&.

static cast from an Lvalue to an Rvalue Reference Is Permitted

Ordinarily, a static_cast can perform only otherwise legitimate conversions (§ 4.11.3, p. 163). However, there is again a special dispensation for rvalue references: Even though we cannot implicitly convert an Ivalue to an rvalue reference, we can explicitly cast an Ivalue to an rvalue reference using static_cast.

Binding an rvalue reference to an Ivalue gives code that operates on the rvalue reference permission to clobber the Ivalue. There are times, such as in our StrVec reallocate function in § 13.6.1 (p. 533), when we know it is safe to clobber an Ivalue. By *letting* us do the cast, the language allows this usage. By *forcing* us to use a cast, the language tries to prevent us from doing so accidentally.

Finally, although we can write such casts directly, it is much easier to use the library move function. Moreover, using std::move consistently makes it easy to find the places in our code that might potentially clobber lyalues.

Exercises Section 16.2.6

Exercise 16.46: Explain this loop from StrVec::reallocate in § 13.5 (p. 530):

Click here to view code image

```
for (size_t i = 0; i != size(); ++i)
    alloc.construct(dest++, std::move(*elem++));
```

16.2.7. Forwarding

Some functions need to forward one or more of their arguments with their types unchanged to another, forwarded-to, function. In such cases, we need to preserve everything about the forwarded arguments, including whether or not the argument type is const, and whether the argument is an Ivalue or an rvalue.

As an example, we'll write a function that takes a callable expression and two additional arguments. Our function will call the given callable with the other two arguments in reverse order. The following is a first cut at our flip function:

- // template that takes a callable and two parameters
- // and calls the given callable with the parameters "flipped"
- // flip1 is an incomplete implementation: top-level const and references are lost

```
template <typename F, typename T1, typename T2>
void flip1(F f, T1 t1, T2 t2)
{
    f(t2, t1);
}
```

This template works fine until we want to use it to call a function that has a reference parameter:

Click here to view code image

```
void f(int v1, int &v2) // note v2 is a reference
{
    cout << v1 << " " << ++v2 << endl;
}</pre>
```

Here f changes the value of the argument bound to v2. However, if we call f through flip1, the changes made by f do not affect the original argument:

Click here to view code image

```
f(42, i); // f changes its argument i
flip1(f, j, 42); // f called through flip1 leaves j unchanged
```

The problem is that j is passed to the t1 parameter in flip1. That parameter has is a plain, nonreference type, int, not an int&. That is, the instantiation of this call to flip1 is

Click here to view code image

```
void flip1(void(*fcn)(int, int&), int t1, int t2);
```

The value of j is copied into t1. The reference parameter in f is bound to t1, not to j.

Defining Function Parameters That Retain Type Information

To pass a reference through our flip function, we need to rewrite our function so that its parameters preserve the "Ivalueness" of its given arguments. Thinking ahead a bit, we can imagine that we'd also like to preserve the constness of the arguments as well.

We can preserve all the type information in an argument by defining its corresponding function parameter as an rvalue reference to a template type parameter. Using a reference parameter (either Ivalue or rvalue) lets us preserve constness, because the const in a reference type is low-level. Through reference collapsing (§ 16.2.5, p. 688), if we define the function parameters as T1&& and T2&&, we can preserve the Ivalue/rvalue property of flip's arguments (§ 16.2.5, p. 687):

```
template <typename F, typename T1, typename T2>
void flip2(F f, T1 &&t1, T2 &&t2)
{
    f(t2, t1);
}
```

As in our earlier call, if we call flip2(f, j, 42), the Ivalue j is passed to the parameter t1. However, in flip2, the type deduced for T1 is int&, which means that the type of t1 collapses to int&. The reference t1 is bound to j. When flip2 calls f, the reference parameter v2 in f is bound to t1, which in turn is bound to j. When f increments v2, it is changing the value of j.

Note

A function parameter that is an rvalue reference to a template type parameter (i.e., T&&) preserves the constness and lvalue/rvalue property of its corresponding argument.

This version of flip2 solves one half of our problem. Our flip2 function works fine for functions that take Ivalue references but cannot be used to call a function that has an rvalue reference parameter. For example:

Click here to view code image

```
void g(int &&i, int& j)
{
     cout << i << " " << j << endl;
}</pre>
```

If we try to call g through flip2, we will be passing the parameter t2 to g's rvalue reference parameter. Even if we pass an rvalue to flip2:

Click here to view code image

```
flip2(g, i, 42); // error: can't initialize int&& from an lvalue
```

what is passed to g will be the parameter named t2 inside flip2. A function parameter, like any other variable, is an Ivalue expression (§ 13.6.1, p. 533). As a result, the call to g in flip2 passes an Ivalue to g's rvalue reference parameter.

Using std::forward to Preserve Type Information in a Call

We can use a new library facility named forward to pass flip2's parameters in a way that preserves the types of the original arguments. Like move, forward is defined in the utility header. Unlike move, forward must be called with an explicit template argument (§ 16.2.2, p. 682). forward returns an rvalue reference to

that explicit argument type. That is, the return type of forward<T> is T&&.

Ordinarily, we use forward to pass a function parameter that is defined as an rvalue reference to a template type parameter. Through reference collapsing on its return type, forward preserves the lvalue/rvalue nature of its given argument:

Click here to view code image

```
template <typename Type> intermediary(Type &&arg)
{
    finalFcn(std::forward<Type>(arg));
    // ...
}
```

Here we use Type—which is deduced from arg—as forward's explicit template argument type. Because arg is an rvalue reference to a template type parameter, Type will represent all the type information in the argument passed to arg. If that argument was an rvalue, then Type is an ordinary (nonreference) type and forward<Type> will return Type&&. If the argument was an Ivalue, then—through reference collapsing—Type itself is an Ivalue reference type. In this case, the return type is an rvalue reference to an Ivalue reference type. Again through reference collapsing—this time on the return type—forward<Type> will return an Ivalue reference type.

Note

When used with a function parameter that is an rvalue reference to template type parameter (T&&), forward preserves all the details about an argument's type.

Using forward, we'll rewrite our flip function once more:

Click here to view code image

```
template <typename F, typename T1, typename T2>
void flip(F f, T1 &&t1, T2 &&t2)
{
    f(std::forward<T2>(t2), std::forward<T1>(t1));
}
```

If we call flip(g, i, 42), i will be passed to g as an int& and 42 will be passed as an int&&.

Note

As with std::move, it's a good idea not to provide a using declaration for std::forward. § 18.2.3 (p. 798) will explain why.

16.3. Overloading and Templates

Function templates can be overloaded by other templates or by ordinary, nontemplate functions. As usual, functions with the same name must differ either as to the number or the type(s) of their parameters.

Exercises Section 16.2.7

Exercise 16.47: Write your own version of the flip function and test it by calling functions that have Ivalue and rvalue reference parameters.

Function matching (§ 6.4, p. 233) is affected by the presence of function templates in the following ways:

- The candidate functions for a call include any function-template instantiation for which template argument deduction (§ 16.2, p. 678) succeeds.
- The candidate function templates are always viable, because template argument deduction will have eliminated any templates that are not viable.
- As usual, the viable functions (template and nontemplate) are ranked by the conversions, if any, needed to make the call. Of course, the conversions used to call a function template are quite limited (§ 16.2.1, p. 679).
- Also as usual, if exactly one function provides a better match than any of the others, that function is selected. However, if there are several functions that provide an equally good match, then:
- If there is only one nontemplate function in the set of equally good matches, the nontemplate function is called.
- If there are no nontemplate functions in the set, but there are multiple function templates, and one of these templates is more specialized than any of the others, the more specialized function template is called.
- Otherwise, the call is ambiguous.

Warning

Correctly defining a set of overloaded function templates requires a good understanding of the relationship among types and of the restricted conversions applied to arguments in template functions.

Writing Overloaded Templates

As an example, we'll build a set of functions that might be useful during debugging. We'll name our debugging functions debug_rep, each of which will return a string representation of a given object. We'll start by writing the most general version of this function as a template that takes a reference to a const object:

Click here to view code image

```
// print any type we don't otherwise handle
template <typename T> string debug_rep(const T &t)
{
   ostringstream ret; // see § 8.3 (p. 321)
   ret << t; // uses T's output operator to print a representation of t
   return ret.str(); // return a copy of the string to which ret is bound
}</pre>
```

This function can be used to generate a string corresponding to an object of any type that has an output operator.

Next, we'll define a version of debug_rep to print pointers:

Click here to view code image

This version generates a string that contains the pointer's own value and calls debug_rep to print the object to which that pointer points. Note that this function can't be used to print character pointers, because the IO library defines a version of the << for char* values. That version of << assumes the pointer denotes a null-terminated character array, and prints the contents of the array, not its address. We'll see in § 16.3 (p. 698) how to handle character pointers.

We might use these functions as follows:

```
string s("hi");
```

```
cout << debug_rep(s) << endl;</pre>
```

For this call, only the first version of debug_rep is viable. The second version of debug_rep requires a pointer parameter, and in this call we passed a nonpointer object. There is no way to instantiate a function template that expects a pointer type from a nonpointer argument, so argument deduction fails. Because there is only one viable function, that is the one that is called.

If we call debug_rep with a pointer:

Click here to view code image

```
cout << debug_rep(&s) << endl;</pre>
```

both functions generate viable instantiations:

- debug_rep(const string* &), which is the instantiation of the first version of debug_rep with T bound to string*
- debug_rep(string*), which is the instantiation of the second version of debug_rep with T bound to string

The instantiation of the second version of debug_rep is an exact match for this call. The instantiation of the first version requires a conversion of the plain pointer to a pointer to const. Normal function matching says we should prefer the second template, and indeed that is the one that is run.

Multiple Viable Templates

As another example, consider the following call:

Click here to view code image

```
const string *sp = &s;
cout << debug_rep(sp) << endl;</pre>
```

Here both templates are viable and both provide an exact match:

- debug_rep(const string* &), the instantiation of the first version of the template with T bound to const string*
- debug_rep(const string*), the instantiation of the second version of the template with T bound to const string

In this case, normal function matching can't distinguish between these two calls. We might expect this call to be ambiguous. However, due to the special rule for overloaded function templates, this call resolves to debug_rep(T*), which is the more specialized template.

The reason for this rule is that without it, there would be no way to call the pointer version of debug_rep on a pointer to const. The problem is that the template debug_rep(const T&) can be called on essentially any type, including pointer types. That template is more general than debug_rep(T*), which can be called only

on pointer types. Without this rule, calls that passed pointers to const would always be ambiguous.

When there are several overloaded templates that provide an equally good match for a call, the most specialized version is preferred.

Nontemplate and Template Overloads

For our next example, we'll define an ordinary nontemplate version of debug_rep to print strings inside double quotes:

Click here to view code image

```
// print strings inside double quotes
string debug_rep(const string &s)
    return '"' + s + '"';
```

Now, when we call debug_rep on a string,

Click here to view code image

```
string s("hi");
cout << debug_rep(s) << endl;</pre>
```

there are two equally good viable functions:

- debug_rep<string>(const string&), the first template with T bound to string
- debug_rep(const string&), the ordinary, nontemplate function

In this case, both functions have the same parameter list, so obviously, each function provides an equally good match for this call. However, the nontemplate version is selected. For the same reasons that the most specialized of equally good function templates is preferred, a nontemplate function is preferred over equally good match(es) to a function template.

Note

When a nontemplate function provides an equally good match for a call as a function template, the nontemplate version is preferred.

Overloaded Templates and Conversions

There's one case we haven't covered so far: pointers to C-style character strings and string literals. Now that we have a version of debug_rep that takes a string, we might expect that a call that passes character strings would match that version. However, consider this call:

Click here to view code image

```
cout << debug_rep("hi world!") << endl; // calls debug_rep(T*)</pre>
```

Here all three of the debug_rep functions are viable:

- debug_rep(const T&), with T bound to char[10]
- debug rep(T*), with T bound to const char
- debug_rep(const string&), which requires a conversion from const char* to string

Both templates provide an exact match to the argument—the second template requires a (permissible) conversion from array to pointer, and that conversion is considered as an exact match for function-matching purposes (§ 6.6.1, p. 245). The nontemplate version is viable but requires a user-defined conversion. That function is less good than an exact match, leaving the two templates as the possible functions to call. As before, the T* version is more specialized and is the one that will be selected.

If we want to handle character pointers as strings, we can define two more nontemplate overloads:

Click here to view code image

```
// convert the character pointers to string and call the string version of debug_rep
string debug_rep(char *p)
{
    return debug_rep(string(p));
}
string debug_rep(const char *p)
{
    return debug_rep(string(p));
}
```

Missing Declarations Can Cause the Program to Misbehave

It is worth noting that for the char* versions of debug_rep to work correctly, a declaration for debug_rep(const string&) must be in scope when these functions are defined. If not, the wrong version of debug_rep will be called:

```
template <typename T> string debug_rep(const T &t);
template <typename T> string debug_rep(T *p);
// the following declaration must be in scope
```

```
// for the definition of debug_rep(char*) to do the right thing
string debug rep(const string &);
string debug_rep(char *p)
     // if the declaration for the version that takes a const string& is not in scope
     // the return will call debug rep(const T&) with T instantiated to string
     return debug_rep(string(p));
```

Ordinarily, if we use a function that we forgot to declare, our code won't compile. Not so with functions that overload a template function. If the compiler can instantiate the call from the template, then the missing declaration won't matter. In this example, if we forget to declare the version of debug_rep that takes a string, the compiler will silently instantiate the template version that takes a const T&.

Declare every function in an overload set before you define any of the functions. That way you don't have to worry whether the compiler will instantiate a call before it sees the function you intended to call.

Exercises Section 16.3

Exercise 16.48: Write your own versions of the debug rep functions.

Exercise 16.49: Explain what happens in each of the following calls:

Click here to view code image

```
template <typename T> void f(T);
template <typename T> void f(const T*);
template <typename T> void g(T);
template <typename T> void g(T*);
int i = 42, *p = &i;
const int ci = 0, *p2 = &ci;
g(42);
         g(p);
               g(ci);
                          g(p2);
f(42);
         f(p);
                 f(ci);
                           f(p2);
```

Exercise 16.50: Define the functions from the previous exercise so that they print an identifying message. Run the code from that exercise. If the calls behave differently from what you expected, make sure you understand why.

16.4. Variadic Templates

A variadic template is a template function or class that can take a varying number of parameters. The varying parameters are known as a parameter pack. There are two kinds of parameter packs: A template parameter pack represents zero or more template parameters, and a function parameter pack represents zero or more function parameters.

We use an ellipsis to indicate that a template or function parameter represents a pack. In a template parameter list, class... or typename... indicates that the following parameter represents a list of zero or more types; the name of a type followed by an ellipsis represents a list of zero or more nontype parameters of the given type. In the function parameter list, a parameter whose type is a template parameter pack is a function parameter pack. For example:

Click here to view code image

```
// Args is a template parameter pack; rest is a function parameter pack
// Args represents zero or more template type parameters
// rest represents zero or more function parameters
template <typename T, typename... Args>
void foo(const T &t, const Args& ... rest);
```

declares that foo is a variadic function that has one type parameter named T and a template parameter pack named Args. That pack represents zero or more additional type parameters. The function parameter list of foo has one parameter, whose type is a const & to whatever type T has, and a function parameter pack named rest. That pack represents zero or more function parameters.

As usual, the compiler deduces the template parameter types from the function's arguments. For a variadic template, the compiler also deduces the number of parameters in the pack. For example, given these calls:

Click here to view code image

the compiler will instantiate four different instances of foo:

Click here to view code image

```
void foo(const int&, const string&, const int&, const
double&);
void foo(const string&, const int&, const char[3]&);
void foo(const double&, const string&);
void foo(const char[3]&);
```

In each case, the type of \mathtt{T} is deduced from the type of the first argument. The remaining arguments (if any) provide the number of, and types for, the additional

arguments to the function.

The sizeof... Operator

When we need to know how many elements there are in a pack, we can use the sizeof... operator. Like sizeof (§ 4.9, p. 156), sizeof... returns a constant expression (§ 2.4.4, p. 65) and does not evaluate its argument:

Click here to view code image

```
template<typename ... Args> void g(Args ... args) {
   cout << sizeof...(Args) << endl; // number of type parameters
   cout << sizeof...(args) << endl; // number of function
parameters
}</pre>
```

Exercises Section 16.4

Exercise 16.51: Determine what sizeof...(Args) and sizeof...(rest) return for each call to foo in this section.

Exercise 16.52: Write a program to check your answer to the previous question.

16.4.1. Writing a Variadic Function Template

In § 6.2.6 (p. 220) we saw that we can use an initializer_list to define a function that can take a varying number of arguments. However, the arguments must have the same type (or types that are convertible to a common type). Variadic functions are used when we know neither the number nor the types of the arguments we want to process. As an example, we'll define a function like our earlier error_msg function, only this time we'll allow the argument types to vary as well. We'll start by defining a variadic function named print that will print the contents of a given list of arguments on a given stream.

Variadic functions are often recursive (§ 6.3.2, p. 227). The first call processes the first argument in the pack and calls itself on the remaining arguments. Our print function will execute this way—each call will print its second argument on the stream denoted by its first argument. To stop the recursion, we'll also need to define a nonvariadic print function that will take a stream and an object:

```
// function to end the recursion and print the last element
// this function must be declared before the variadic version of print is defined
template<typename T>
ostream &print(ostream &os, const T &t)
{
    return os << t; // no separator after the last element in the pack
}
// this version of print will be called for all but the last element in the pack
template <typename T, typename... Args>
ostream &print(ostream &os, const T &t, const Args&... rest)
{
    os << t << ", "; // print the first argument
    return print(os, rest...); // recursive call; print the other
arguments
}</pre>
```

The first version of print stops the recursion and prints the last argument in the initial call to print. The second, variadic, version prints the argument bound to t and calls itself to print the remaining values in the function parameter pack.

The key part is the call to print inside the variadic function:

Click here to view code image

```
return print(os, rest...); // recursive call; print the other arguments
```

The variadic version of our print function takes three parameters: an ostream&, a const T&, and a parameter pack. Yet this call passes only two arguments. What happens is that the first argument in rest gets bound to t. The remaining arguments in rest form the parameter pack for the next call to print. Thus, on each call, the first argument in the pack is removed from the pack and becomes the argument bound to t. That is, given:

Click here to view code image

```
print(cout, i, s, 42); // two parameters in the pack
```

the recursion will execute as follows:

Call			t	rest	_
print(cout,	i, s,	42)	i	s, 42	-
print(cout,	s, 42)	S	42	
print(cout,	42) ca	lls the nona	variadic ver	sion of print	

The first two calls can match only the variadic version of print because the nonvariadic version isn't viable. These calls pass four and three arguments, respectively, and the nonvariadic print takes only two arguments.

For the last call in the recursion, print(cout, 42), both versions of print are viable. This call passes exactly two arguments, and the type of the first argument is ostream&. Thus, the nonvariadic version of print is viable.

The variadic version is also viable. Unlike an ordinary argument, a parameter pack can be empty. Hence, the variadic version of print can be instantiated with only two parameters: one for the ostream& parameter and the other for the const T& parameter.

Both functions provide an equally good match for the call. However, a nonvariadic template is more specialized than a variadic template, so the nonvariadic version is chosen for this call (§ 16.3, p. 695).

Warning

A declaration for the nonvariadic version of print must be in scope when the variadic version is defined. Otherwise, the variadic function will recurse indefinitely.

Exercises Section 16.4.1

Exercise 16.53: Write your own version of the print functions and test them by printing one, two, and five arguments, each of which should have different types.

Exercise 16.54: What happens if we call print on a type that doesn't have an << operator?

Exercise 16.55: Explain how the variadic version of print would execute if we declared the nonvariadic version of print after the definition of the variadic version.

16.4.2. Pack Expansion

Aside from taking its size, the only other thing we can do with a parameter pack is to **expand** it. When we expand a pack, we also provide a **pattern** to be used on each expanded element. Expanding a pack separates the pack into its constituent elements, applying the pattern to each element as it does so. We trigger an expansion by putting an ellipsis (. . .) to the right of the pattern.

For example, our print function contains two expansions:

```
template <typename T, typename... Args>
ostream &
print(ostream &os, const T &t, const Args&... rest)// expand
```

The first expansion expands the template parameter pack and generates the function parameter list for print. The second expansion appears in the call to print. That pattern generates the argument list for the call to print.

The expansion of Args applies the pattern const Args& to each element in the template parameter pack Args. The expansion of this pattern is a comma-separated list of zero or more parameter types, each of which will have the form const type&. For example:

Click here to view code image

```
print(cout, i, s, 42); // two parameters in the pack
```

The types of the last two arguments along with the pattern determine the types of the trailing parameters. This call is instantiated as

Click here to view code image

```
ostream&
print(ostream&, const int&, const string&, const int&);
```

The second expansion happens in the (recursive) call to print. In this case, the pattern is the name of the function parameter pack (i.e., rest). This pattern expands to a comma-separated list of the elements in the pack. Thus, this call is equivalent to

```
print(os, s, 42);
```

Understanding Pack Expansions

The expansion of the function parameter pack in print just expanded the pack into its constituent parts. More complicated patterns are also possible when we expand a function parameter pack. For example, we might write a second variadic function that calls debug_rep (§ 16.3, p. 695) on each of its arguments and then calls print to print the resulting strings:

Click here to view code image

```
// call debug_rep on each argument in the call to print
template <typename... Args>
ostream &errorMsg(ostream &os, const Args&... rest)
{
    // print(os, debug_rep(a1), debug_rep(a2), ..., debug_rep(an)
    return print(os, debug_rep(rest)...);
}
```

The call to print uses the pattern debug_rep(rest). That pattern says that we

want to call debug_rep on each element in the function parameter pack rest. The resulting expanded pack will be a comma-separated list of calls to debug_rep. That is, a call such as

Click here to view code image

```
errorMsg(cerr, fcnName, code.num(), otherData, "other",
item);
```

will execute as if we had written

Click here to view code image

In contrast, the following pattern would fail to compile:

Click here to view code image

```
// passes the pack to debug_rep; print(os, debug_rep(a1, a2, ..., an))
print(os, debug_rep(rest...)); // error: no matching function to call
```

The problem here is that we expanded rest in the call to debug_rep. This call would execute as if we had written

Click here to view code image

In this expansion, we attempted to call debug_rep with a list of five arguments. There is no version of debug_rep that matches this call. The debug_rep function is not variadic and there is no version of debug_rep that has five parameters.

Note

The pattern in an expansion applies separately to each element in the pack.

Exercises Section 16.4.2

Exercise 16.56: Write and test a variadic version of errorMsg.

Exercise 16.57: Compare your variadic version of errorMsg to the error_msg function in § 6.2.6 (p. 220). What are the advantages and disadvantages of each approach?

16.4.3. Forwarding Parameter Packs

Under the new standard, we can use variadic templates together with forward to write functions that pass their arguments unchanged to some other function. To illustrate such functions, we'll add an emplace_back member to our StrVec class (§ 13.5, p. 526). The emplace_back member of the library containers is a variadic member template (§ 16.1.4, p. 673) that uses its arguments to construct an element directly in space managed by the container.

Our version of emplace_back for StrVec will also have to be variadic, because string has a number of constructors that differ in terms of their parameters. Because we'd like to be able to use the string move constructor, we'll also need to preserve all the type information about the arguments passed to emplace_back.

As we've seen, preserving type information is a two-step process. First, to preserve type information in the arguments, we must define <code>emplace_back</code>'s function parameters as rvalue references to a template type parameter (§ 16.2.7, p. 693):

Click here to view code image

```
class StrVec {
public:
    template <class... Args> void emplace_back(Args&&...);
    // remaining members as in § 13.5 (p. 526)
};
```

The pattern in the expansion of the template parameter pack, &&, means that each function parameter will be an rvalue reference to its corresponding argument.

Second, we must use forward to preserve the arguments' original types when emplace_back passes those arguments to construct (§ 16.2.7, p. 694):

Click here to view code image

```
template <class... Args>
inline
void StrVec::emplace_back(Args&&... args)
{
    chk_n_alloc(); // reallocates the StrVec if necessary
    alloc.construct(first_free++,
std::forward<Args>(args)...);
}
```

The body of emplace_back calls chk_n_alloc (§ 13.5, p. 526) to ensure that there is enough room for an element and calls construct to create an element in the first_free spot. The expansion in the call to construct:

```
std::forward<Args>(args)...
```

expands both the template parameter pack, Args, and the function parameter pack, args. This pattern generates elements with the form

```
std::forward < T_i > (t_i)
```

where T_i represents the type of the *i*th element in the template parameter pack and t_i represents the *i*th element in the function parameter pack. For example, assuming svec is a StrVec, if we call

Click here to view code image

```
svec.emplace_back(10, 'c'); // adds ccccccccc as a new last element
the pattern in the call to construct will expand to
```

Click here to view code image

```
std::forward<int>(10), std::forward<char>(c)
```

By using forward in this call, we guarantee that if emplace_back is called with an rvalue, then construct will also get an rvalue. For example, in this call:

Click here to view code image

```
svec.emplace_back(s1 + s2); // uses the move constructor
```

the argument to emplace_back is an rvalue, which is passed to construct as

Click here to view code image

```
std::forward<string>(string("the end"))
```

The result type from forward<string> is string&&, so construct will be called with an rvalue reference. The construct function will, in turn, forward this argument to the string move constructor to build this element.

Advice: Forwarding and Variadic Templates

Variadic functions often forward their parameters to other functions. Such functions typically have a form similar to our emplace_back function:

Click here to view code image

```
// fun has zero or more parameters each of which is
// an rvalue reference to a template parameter type
template<typename... Args>
void fun(Args&&... args) // expands Args as a list of rvalue references
{
    // the argument to work expands both Args and args
    work(std::forward<Args>(args)...);
}
```

Here we want to forward all of fun's arguments to another function named work that presumably does the real work of the function. Like our call to construct inside emplace_back, the expansion in the call to work

expands both the template parameter pack and the function parameter pack.

Because the parameters to fun are rvalue references, we can pass arguments of any type to fun; because we use std::forward to pass those arguments, all type information about those arguments will be preserved in the call to work.

Exercises Section 16.4.3

Exercise 16.58: Write the emplace_back function for your StrVec class and for the Vec class that you wrote for the exercises in § 16.1.2 (p. 668).

Exercise 16.59: Assuming s is a string, explain svec.emplace_back(s).

Exercise 16.60: Explain how make_shared (§ 12.1.1, p. 451) works.

Exercise 16.61: Define your own version of make_shared.

16.5. Template Specializations

It is not always possible to write a single template that is best suited for every possible template argument with which the template might be instantiated. In some cases, the general template definition is simply wrong for a type: The general definition might not compile or might do the wrong thing. At other times, we may be able to take advantage of some specific knowledge to write more efficient code than would be instantiated from the template. When we can't (or don't want to) use the template version, we can define a specialized version of the class or function template.

Our compare function is a good example of a function template for which the general definition is not appropriate for a particular type, namely, character pointers. We'd like compare to compare character pointers by calling stromp rather than by comparing the pointer values. Indeed, we have already overloaded the compare function to handle character string literals (§ 16.1.1, p. 654):

Click here to view code image

```
// first version; can compare any two types
template <typename T> int compare(const T&, const T&);
// second version to handle string literals
template<size_t N, size_t M>
int compare(const char (&)[N], const char (&)[M]);
```

However, the version of compare that has two nontype template parameters will be called only when we pass a string literal or an array. If we call compare with

character pointers, the first version of the template will be called:

Click here to view code image

There is no way to convert a pointer to a reference to an array, so the second version of compare is not viable when we pass p1 and p2 as arguments.

To handle character pointers (as opposed to arrays), we can define a **template specialization** of the first version of compare. A specialization is a separate definition of the template in which one or more template parameters are specified to have particular types.

Defining a Function Template Specialization

When we specialize a function template, we must supply arguments for every template parameter in the original template. To indicate that we are specializing a template, we use the keyword template followed by an empty pair of angle brackets (< >). The empty brackets indicate that arguments will be supplied for all the template parameters of the original template:

Click here to view code image

```
// special version of compare to handle pointers to character arrays
template <>
int compare(const char* const &p1, const char* const &p2)
{
    return strcmp(p1, p2);
}
```

The hard part in understanding this specialization is the function parameter types. When we define a specialization, the function parameter type(s) must match the corresponding types in a previously declared template. Here we are specializing:

Click here to view code image

```
template <typename T> int compare(const T&, const T&);
```

in which the function parameters are references to a const type. As with type aliases, the interaction between template parameter types, pointers, and const can be surprising (§ 2.5.1, p. 68).

We want to define a specialization of this function with T as const char*. Our function requires a reference to the const version of this type. The const version of a pointer type is a constant pointer as distinct from a pointer to const (§ 2.4.2, p. 63). The type we need to use in our specialization is const char* const &, which is a reference to a const pointer to const char.

Function Overloading versus Template Specializations

When we define a function template specialization, we are essentially taking over the job of the compiler. That is, we are supplying the definition to use for a specific instantiation of the original template. It is important to realize that a specialization is an instantiation; it is not an overloaded instance of the function name.

Specializations instantiate a template; they do not overload it. As a result, specializations do not affect function matching.

Whether we define a particular function as a specialization or as an independent, nontemplate function can impact function matching. For example, we have defined two versions of our compare function template, one that takes references to array parameters and the other that takes const T&. The fact that we also have a specialization for character pointers has no impact on function matching. When we call compare on a string literal:

compare("hi", "mom")

both function templates are viable and provide an equally good (i.e., exact) match to the call. However, the version with character array parameters is more specialized (§ 16.3, p. 695) and is chosen for this call.

Had we defined the version of compare that takes character pointers as a plain nontemplate function (rather than as a specialization of the template), this call would resolve differently. In this case, there would be three viable functions: the two templates and the nontemplate character-pointer version. All three are also equally good matches for this call. As we've seen, when a nontemplate provides an equally good match as a function template, the nontemplate is selected (§ 16.3, p. 695)

Key Concept: Ordinary Scope Rules Apply to Specializations

In order to specialize a template, a declaration for the original template must be in scope. Moreover, a declaration for a specialization must be in scope before any code uses that instantiation of the template.

With ordinary classes and functions, missing declarations are (usually) easy to find—the compiler won't be able to process our code. However, if a specialization declaration is missing, the compiler will usually generate code using the original template. Because the compiler can often instantiate the original template when a specialization is missing, errors in declaration order between a template and its specializations are easy to make but hard to find.

It is an error for a program to use a specialization and an instantiation of

the original template with the same set of template arguments. However, it is an error that the compiler is unlikely to detect.

* Best Practices

Templates and their specializations should be declared in the same header file. Declarations for all the templates with a given name should appear first, followed by any specializations of those templates.

Class Template Specializations

In addition to specializing function templates, we can also specialize class templates. As an example, we'll define a specialization of the library hash template that we can use to store Sales_data objects in an unordered container. By default, the unordered containers use hash<key_type> (§ 11.4, p. 444) to organize their elements. To use this default with our own data type, we must define a specialization of the hash template. A specialized hash class must define

- An overloaded call operator (§ 14.8, p. 571) that returns a size_t and takes an object of the container's key type
- Two type members, result_type and argument_type, which are the return and argument types, respectively, of the call operator
- The default constructor and a copy-assignment operator (which can be implicitly defined (§ 13.1.2, p. 500))

The only complication in defining this hash specialization is that when we specialize a template, we must do so in the same namespace in which the original template is defined. We'll have more to say about namespaces in § 18.2 (p. 785). For now, what we need to know is that we can add members to a namespace. To do so, we must first open the namespace:

Click here to view code image

```
// open the std namespace so we can specialize std::hash
namespace std {
    // close the std namespace; note: no semicolon after the close curly
```

Any definitions that appear between the open and close curlies will be part of the std namespace.

The following defines a specialization of hash for Sales_data:

Click here to view code image

```
open the std namespace so we can specialize std::hash
namespace std {
template <>
                       // we're defining a specialization with
struct hash<Sales_data> // the template parameter of Sales_data
     // the type used to hash an unordered container must define these types
     typedef size_t result_type;
      typedef Sales_data argument_type; // by default, this type needs
==
     size_t operator()(const Sales_data& s) const;
     // our class uses synthesized copy control and default constructor
size t
hash<Sales_data>::operator()(const Sales_data& s) const
     return hash<string>()(s.bookNo)
             hash<unsigned>()(s.units_sold) ^
             hash<double>()(s.revenue);
  // close the std namespace; note: no semicolon after the close curly
```

Our hash<Sales_data> definition starts with template<>, which indicates that we are defining a fully specialized template. The template we're specializing is named hash and the specialized version is hash<Sales_data>. The members of the class follow directly from the requirements for specializing hash.

As with any other class, we can define the members of a specialization inside the class or out of it, as we did here. The overloaded call operator must define a hashing function over the values of the given type. This function is required to return the same result every time it is called for a given value. A good hash function will (almost always) yield different results for objects that are not equal.

Here, we delegate the complexity of defining a good hash function to the library. The library defines specializations of the hash class for the built-in types and for many of the library types. We use an (unnamed) hash<string> object to generate a hash code for bookNo, an object of type hash<unsigned> to generate a hash from units_sold, and an object of type hash<double> to generate a hash from revenue. We exclusive or (§ 4.8, p. 154) these results to form an overall hash code for the given Sales_data object.

It is worth noting that we defined our hash function to hash all three data members so that our hash function will be compatible with our definition of operator== for Sales_data (§ 14.3.1, p. 561). By default, the unordered containers use the specialization of hash that corresponds to the key_type along with the equality operator on the key type.

Assuming our specialization is in scope, it will be used automatically when we use Sales_data as a key to one of these containers:

Click here to view code image

```
// uses hash<Sales_data> and Sales_data operator==from § 14.3.1 (p. 561)
unordered_multiset<Sales_data> SDset;
```

Because hash<Sales_data> uses the private members of Sales_data, we must make this class a friend of Sales_data:

Click here to view code image

```
template <class T> class std::hash;  // needed for the friend
declaration
class Sales_data {
friend class std::hash<Sales_data>;
    // other members as before
};
```

Here we say that the specific instantiation of hash<Sales_data> is a friend. Because that instantiation is defined in the std namespace, we must remember to that this hash type is defined in the std namespace. Hence, our friend declaration refers to std::hash.

Note

To enable users of Sales_data to use the specialization of hash, we should define this specialization in the Sales_data header.

Class-Template Partial Specializations

Differently from function templates, a class template specialization does not have to supply an argument for every template parameter. We can specify some, but not all, of the template parameters or some, but not all, aspects of the parameters. A class template **partial specialization** is itself a template. Users must supply arguments for those template parameters that are not fixed by the specialization.

Note

We can partially specialize only a class template. We cannot partially specialize a function template.

In § 16.2.3 (p. 684) we introduced the library remove_reference type. That template works through a series of specializations:

Click here to view code image

// original, most general template

```
template <class T> struct remove_reference
    typedef T type;
};

// partial specializations that will be used for lvalue and rvalue references
template <class T> struct remove_reference<T&> // lvalue
references
    { typedef T type; };
template <class T> struct remove_reference<T&> // rvalue
references
    { typedef T type; };
```

The first template defines the most general version. It can be instantiated with any type; it uses its template argument as the type for its member named type. The next two classes are partial specializations of this original template.

Because a partial specialization is a template, we start, as usual, by defining the template parameters. Like any other specialization, a partial specialization has the same name as the template it specializes. The specialization's template parameter list includes an entry for each template parameter whose type is not completely fixed by this partial specialization. After the class name, we specify arguments for the template parameters we are specializing. These arguments are listed inside angle brackets following the template name. The arguments correspond positionally to the parameters in the original template.

The template parameter list of a partial specialization is a subset of, or a specialization of, the parameter list of the original template. In this case, the specializations have the same number of parameters as the original template. However, the parameter's type in the specializations differ from the original template. The specializations will be used for Ivalue and rvalue reference types, respectively:

Click here to view code image

```
int i;
// decltype(42) is int, uses the original template
remove_reference<decltype(42)>::type a;
// decltype(i) is int&, uses first (T&) partial specialization
remove_reference<decltype(i)>::type b;
// decltype(std::move(i)) is int&&, uses second (i.e., T&&) partial specialization
remove_reference<decltype(std::move(i))>::type c;
```

All three variables, a, b, and c, have type int.

Specializing Members but Not the Class

Rather than specializing the whole template, we can specialize just specific member function(s). For example, if Foo is a template class with a member Bar, we can specialize just that member:

Click here to view code image

Here we are specializing just one member of the Foo<int> class. The other members of Foo<int> will be supplied by the Foo template:

Click here to view code image

```
Foo<string> fs;  // instantiates Foo<string>::Foo()
fs.Bar();  // instantiates Foo<string>::Bar()
Foo<int> fi;  // instantiates Foo<int>::Foo()
fi.Bar();  // uses our specialization of Foo<int>::Bar()
```

When we use Foo with any type other than int, members are instantiated as usual. When we use Foo with int, members other than Bar are instantiated as usual. If we use the Bar member of Foo<int>, then we get our specialized definition.

Exercises Section 16.5

Exercise 16.62: Define your own version of hash<Sales_data> and define an unordered_multiset of Sales_data objects. Put several transactions into the container and print its contents.

Exercise 16.63: Define a function template to count the number of occurrences of a given value in a vector. Test your program by passing it a vector of doubles, a vector of ints, and a vector of strings.

Exercise 16.64: Write a specialized version of the template from the previous exercise to handle vector<const char*> and a program that uses this specialization.

Exercise 16.65: In § 16.3 (p. 698) we defined overloaded two versions of debug_rep one had a const char* and the other a char* parameter. Rewrite these functions as specializations.

Exercise 16.66: What are the advantages and disadvantages of overloading these debug_rep functions as compared to defining specializations?

Exercise 16.67: Would defining these specializations affect function matching for debug_rep? If so, how? If not, why not?

Chapter Summary

Templates are a distinctive feature of C++ and are fundamental to the library. A template is a blueprint that the compiler uses to generate specific class types or functions. This process is called instantiation. We write the template once, and the compiler instantiates the template for the type(s) or value(s) with which we use the template.

We can define both function templates and class templates. The library algorithms are function templates and the library containers are class templates.

An explicit template argument lets us fix the type or value of one or more template parameters. Normal conversions are applied to parameters that have an explicit template argument.

A template specialization is a user-provided instantiation of a template that binds one or more template parameters to specified types or values. Specializations are useful when there are types that we cannot use (or do not want to use) with the template definition.

A major part of the latest release of the C++ standard is variadic templates. A variadic template can take a varying number and types of parameters. Variadic templates let us write functions, such as the container emplace members and the library make_shared function, that pass arguments to an object's constructor.

Defined Terms

class template Definition from which specific classes can be instantiated. Class templates are defined using the template keyword followed by a commaseparated list of one or more template parameters enclosed in < and > brackets, followed by a class definition.

default template arguments A type or a value that a template uses if the user does not supply a corresponding template argument.

explicit instantiation A declaration that supplies explicit arguments for all the template parameters. Used to guide the instantiation process. If the declaration is extern, the template will not be instantiated; otherwise, the template is instantiated with the specified arguments. There must be a nonextern explicit instantiation somewhere in the program for every extern template declaration.

explicit template argument Template argument supplied by the user in a call to a function or when defining a template class type. Explicit template arguments are supplied inside angle brackets immediately following the template's name.

function parameter pack Parameter pack that represents zero or more function

parameters.

function template Definition from which specific functions can be instantiated. A function template is defined using the template keyword followed by a commaseparated list of one or more template parameters enclosed in < and > brackets, followed by a function definition.

instantiate Compiler process whereby the actual template argument(s) are used to generate a specific instance of the template in which the parameter(s) are replaced by the corresponding argument(s). Functions are instantiated automatically based on the arguments used in a call. We must supply explicit template arguments whenever we use a class template.

instantiation Class or function generated by the compiler from a template.

member template Member function that is a template. A member template may not be virtual.

nontype parameter A template parameter that represents a value. Template arguments for nontype template parameters must be constant expressions.

pack expansion Process by which a parameter pack is replaced by the corresponding list of its elements.

parameter pack Template or function parameter that represents zero or more parameters.

partial specialization Version of a class template in which some some but not all of the template parameters are specified or in which one or more parameters are not completely specified.

pattern Defines the form of each element in an expanded parameter pack.

template argument Type or value used to instantiate a template parameter.

template argument deduction Process by which the compiler determines which function template to instantiate. The compiler examines the types of the arguments that were specified using a template parameter. It automatically instantiates a version of the function with those types or values bound to the template parameters.

template parameter Name specified in the template parameter list that may be used inside the definition of a template. Template parameters can be type or nontype parameters. To use a class template, we must supply explicit arguments for each template parameter. The compiler uses those types or values to instantiate a version of the class in which uses of the parameter(s) are replaced by the actual argument(s). When a function template is used, the compiler deduces the template arguments from the arguments in the call and instantiates a specific function using the deduced template arguments.

template parameter list List of parameters, separated by commas, to be used in the definition or declaration of a template. Each parameter may be a type or nontype parameter.

template parameter pack Parameter pack that represents zero or more template parameters.

template specialization Redefinition of a class template, a member of a class template, or a function template, in which some (or all) of the template parameters are specified. A template specialization may not appear until after the base template that it specializes has been declared. A template specialization must appear before any use of the template with the specialized arguments. Each template parameter in a function template must be completely specialized.

type parameter Name used in a template parameter list to represent a type. Type parameters are specified following the keyword typename or class.

type transformation Class templates defined by the library that transform their given template type parameter to a related type.

variadic template Template that takes a varying number of template arguments. A template parameter pack is specified using an elipsis (e.g., class..., typename..., or type-name...).

Part IV: Advanced Topics

Contents

Chapter 17 Specialized Library Facilities

Chapter 18 Tools for Large Programs

Chapter 19 Specialized Tools and Techniques

Part IV covers additional features that, although useful in the right context, are not needed by every C++ programmer. These features divide into two clusters: those that are useful for large-scale problems and those that are applicable to specialized problems rather than general ones. Features for specialized problems occur both in the language, the topic of Chapter 19, and in the library, Chapter 17.

In Chapter 17 we cover four special-purpose library facilities: the bitset class and three new library facilities: tuples, regular expressions, and random numbers. We'll also look at some of the less commonly used parts of the IO library.

Chapter 18 covers exception handling, namespaces, and multiple inheritance. These features tend to be most useful in the context of large-scale problems.

Even programs simple enough to be written by a single author can benefit from
